Simple congruence prover

Replaces a goal of the shape:

$$f\ x\ (g\ y)\ (\lambda x. x + 1) = f\ x'\ (i\ y')\ (\lambda z. z + Suc\ 0)$$

by

$$x = x'\ g\ y = i\ y'\ 1 = Suc\ 0$$

The tactic essentially applies $\llbracket ?f = ?g; ?x = ?y \rrbracket \implies ?f\ ?x = ?g\ ?y$, but using first-order matching.

The core notions on spec monads are

- Properties of a monad: *runs-to*, *runs-to-partial*
- Refinement / Simulation of monads: *refines*, *rel-spec* and *rel-spec-monad*.

It is considered good style to use these more abstract concepts as much as possible.

Next we introduce some notions that are more in a 'pointwise' spirit in the sense that they talk about a particular outcome of a monadic computation, e.g. that a particular state is a reachable outcome of a monadic computation.

There is nothing *wrong* with these notions but we consider them as less elegant and more 'brute force'. So we encourage to think twice before using them and prefer the more abstract notions.

primrec *outcomes* :: 'a post-state \Rightarrow 'a set **where**
outcomes Failure = {}
| *outcomes (Success X)* = X

16.11 *succeeds and reaches*

definition *succeeds* :: ('e::default, 'a, 's) spec-monad \Rightarrow 's \Rightarrow bool **where**
succeeds f s \longleftrightarrow *run f s* $\neq \top$

definition *reaches* :: ('e::default, 'a, 's) spec-monad \Rightarrow 's \Rightarrow ('e, 'a) exception-or-result
 \Rightarrow 's \Rightarrow bool **where**
reaches f s r' s' \longleftrightarrow $(r', s') \in \text{outcomes (run f s)}$

There seems to a similarity between what happens in HOL with the dualism of sets as type vs. the characterisation as predicate as expressed in *Collect*. Similar 'a post-state has a set in the *Success* case. In particular with *holds-post-state* we switch to the predicate view. Which is then continued in *runs-to* which is the predicate view and the set view with *reaches*, which is more the element wise set view similar to $x \in X$ and finally culminates in $(?f = ?g) = (\forall P s. (?f \cdot s \ \S P \ \S) = (?g \cdot s \ \S P \ \S))$. The predicate view seems to be the one we finally aim for. So maybe we could get completely rid of the set like things and start of with a predicate already in 'a post-state?

  imports AutoCorres-Utils  
begin
```

ATTENTION: to activate these methods use the following line:

```
setup  $\langle$ Raw-Simplifier.set-trace-ops Simp-Trace.trace-ops $\rangle$ 
```

Provide a tactic wrapper to activate simplifier tracing and produce a statistic how many conditional rules were tried for how long. Also provides a shorthand for simp trace activation by adding *T* to the method name: *simpT simp-allT autoT*

We want to express that certain portions of the heap (typing and values) are 'irrelevant', in particular regarding (free) stack space. The notion of 'irrelevant' is a bit vague, it means that the behaviour of the program does not depend on those locations and also that it does not modify those locations. Moreover, we prefer an abstraction function rather than an relation between states to avoid admissibility issues for refinement.

definition *frame:: addr set \Rightarrow 's \Rightarrow 's \Rightarrow 's* **where**

frame $A \ s_0 \ s =$
 $hmem\text{-upd } (\lambda h. \text{override-on } h \ (hmem \ s_0) \ (A \cup \text{stack-free } (h\text{td } s)))$
 $(h\text{td-upd } (\lambda d. \text{override-on } d \ (h\text{td } s_0) \ (A - \text{stack-free } (h\text{td } s))) \ s)$

The standard use case we have in mind is $A \cap \text{stack-free } (h\text{td } s) = \{\}$, hence $A - \text{stack-free } (h\text{td } s) = A$, but nevertheless the intuition is:

- stack free typing from s is preserved, the framed sate has at least as many stack free addresses as the original one. So we can simulate any stack allocation.
- heap values for stack free and A are taken from reference state s_0 , this captures that we do not depend on the original values in s for those addresses.
- typing for allocations in A is taken from reference state s_0 , this captures that we do not depend on the original typing in s for those addresses.

By taking the same reference state s_0 to frame two states s and s' , we can express that the 'irrelevant' parts of the heap did not change in the respective framed states $\text{frame } A \ s_0 \ s$ and $\text{frame } A \ s_0 \ s'$.

21.1.1 Syntax $PTR\text{-VALID}('a)$

context *open-types*

begin

We want to provide syntax that makes the type of *ptr-valid* visible on the term level for interpretations of the *open-types*. This is a bit tricky as Isabelle does not (yet) provide local syntax and local print / parse translations. We

implement it by a combination of theory level syntax and translations and a local declarations for the interpretations.

end

syntax

-ptr-valid :: *type* \Rightarrow *logic* ((1PTR'-VALID)/(1'(-')))

ML \langle

structure *Ptr-Valid-Translation* =

struct

val *show-ptr-valid* = *Attrib.setup-config-bool* @{*binding* *show-ptr-valid*} (*K true*)

  in
    [(syntax-const ⟨-ptr-valid⟩, ptr-valid-tr)]
  end

```

```

setup ⟨Ptr-Valid-Translation.add-ptr-valid-print-translation NONE⟩

```

This theory level setup actually provides the local syntax when working within a locale like *open-types*. The *print-translation* is triggered on constant (abbreviation) *local.ptr-valid*

```

context open-types

```

```

begin

```

```

term PTR-VALID(32 word) — Works in both directions by theory level setup above.

```

```

declaration ⟨fn phi => fn context =>

```

```

  let
    val ptr-valid = Morphism.term phi term ⟨ptr-valid⟩
    val ptr-valid-name = Morphism.binding phi (Binding.make (Ptr-Valid-Translation.ptr-validN,
here))
    |> Binding.name-of

```

```

    val opt = SOME {ptr-valid = ptr-valid, ptr-valid-name = ptr-valid-name}
  in
    context |> Context.mapping (Ptr-Valid-Translation.add-ptr-valid-print-translation
opt) I
  end

```

This declaration provides the setup for global interpretations. The print translation is triggered on constant (abbreviation) $\langle instance-name \rangle.ptr\text{-}valid$ introduced by the interpretation. Keep in mind, that when printing a term on the internal $PTR\text{-}VALID('a)$ first the notations / abbreviations are applied. These introduce the syntactic constant $PTR\text{-}VALID('a)$ on which the translation then triggers.

end

21.1.2 Syntax $IS\text{-}VALID('a)$

context *open-types*
begin

Building on top of $PTR\text{-}VALID$ we provide syntax that also takes the *heap-typing* of lifted globals into account: $IS\text{-}VALID(32\text{ word})\ s\ p$ is translated to $PTR\text{-}VALID('a)\ (heap\text{-}typing\ s)\ p$ Note that *heap-typing* is a field of the lifted globals record that is defined later.

23.1 Synthesize Rules Setup

Canonical format for the currently supported monads: *refines C (lift-to-spec A) s t (rel-prod rel-res (=))* where *lift-spec*, *rel-res* is

- pure (Pure function): *return, rel-liftE*
- gets (Reader monad): *gets, rel-liftE*
- option (Option monad): *gets-the, rel-liftE*
- nondet: *id (ommitted), rel-liftE*
- exit:
 - *id (ommitted), rel-xval rel-Nonlocal (=)*
 - *id (ommitted), rel-xval (=) (=)* for those function that were lifted by the IO phase.

synthesize-rules *pure and reader and option and nondet and exit*

add-synthesize-pattern *pure and reader and option and nondet and exit where*
refines-pure-synth = ⟨Trueprop (refines ?f ((return ?f')::(?'a, ?'s) res-monad) - - ?R)⟩ (f')

add-synthesize-pattern *reader and option and nondet and exit where*
refines-reader-synth = ⟨Trueprop (refines ?f (gets ?f') - - ?R)⟩ (f')

add-synthesize-pattern *option where*
refines-option-synth = ⟨Trueprop (refines ?f (gets-the ?f') - - ?R)⟩ (f')

add-synthesize-pattern *nondet and exit where*
refines-nondet-synth = ⟨Trueprop (refines ?f ?f' - - ?R)⟩ (f') and

rel-liftE-nondet-synth = ⟨Trueprop (rel-liftE ?x ?x')⟩ (x') and
rel-sum-nondet-synth = ⟨Trueprop (rel-sum - - ?x ?x')⟩ (x') and
rel-sum-nondet-synth = ⟨Trueprop (rel-xval - - ?x ?x')⟩ (x') and
rel-compp-nondet-synth = ⟨Trueprop ((- OO -) ?x ?x')⟩ (x') and
rel-map-synth = ⟨Trueprop (rel-map ?f ?x ?x')⟩ (x') and
rel-eq-nondet-synth = ⟨Trueprop (?x = ?x')⟩ (x')

add-synthesize-pattern *exit where*

rel-Nondet-exit-synth = ⟨Trueprop (rel-Nonlocal ?x ?x')⟩ (x')

Recursive functions are defined using **fixed-point**. The option, nondet and exit monad are setup to handle these definitions. Hence the minimal monad for recursive functions is the option monad.

A best-effort approach to determine the simplest possible 'monad' for the final definition is implemented. We first try to define a function into the most restrictive monad and if that fails successively try more expressive monads until we finally hit the most expressive monad. In the original autocorres version this phase was based on equations and not on a simulation relation as all the other autocorres phases. With the switch to model recursive functions with a CCPO **fixed-point** instead of **function** with an explicit measure parameter this did no longer work, as equations are not *ccpo.admissible*. Fortunately simulation is admissible, so we changed this phase to *refines*, cf: `Refines_Spec.thy`. So the main purpose of this theory is to set up the available target monads by applying some meta information: `monad_types.ML`.

The correspondence equations have the format:

(*) $p = L2\text{-call-lift } p'$

where *L2-call-lift* depends on the (simpler) target monad and lifts the program p' from that simpler monad to the fully fledged monad we start with:

The program p is the definition we have from the last layer of autocorres (WA). The final definition will refer to p' .

For the code to work *L2-call-lift* has to be a distinct constant, as some matching is performed on that assumption. That is why some new definitions are introduced below.

Note that the final (most expressive) monad is characterised by the lifting function is *lift-exit-status* which merely removes the exception handling artefact from SIMPL by extracting the exception value $'a$ from $'a\ c\text{-exntype}$. So it should be sufficiently expressive for any input C program.

When the proof for a certain monad fails it can either have a good reason (as the input function is just not expressible in that particular monad) or it can fail because the implementation is missing some rules.

Note some peculiarities on the current state of affairs:

- When a guard remains (e.g. bounds for an integer) you end up at least in the option monad (to model the possible failure).
- As recursive functions are currently implemented with **fixed-point** they are at least in the option monad.

24.2 Monad simplification with custom congruence rules

```

context open-types
begin

```

We supply a custom simplification method for spec monad expressions that gathers and propagates information from conditions and guards while descending into the term. The core motivation is to clean up repeated occurrences of $PTR-VALID('a)$ (*heap-typing* s) p . Although this is a state dependent predicate it stays invariant as long as the typing does not change. So the goal of the simplification method is to prove preservation of such predicates while descending into the term. Supplying congruence rules to the simplifier is unfortunately not enough as we want to keep control over what kind of invariants are propagated. Unfortunately the simplifier has no concept of a *congps* that are triggered when descending into the term only the *simprocs* which are triggered by the usual bottom up simplifier strategy. To work around this limitation we implement *congps* by *simprocs*:

- We block the simplifier to descend into compound terms by adding trivial congruence rules to the simplifier, like $f \gg = g \equiv f \gg = g$
- We add a simproc that then triggers on the $f \gg = g$ and manually extends the context and invokes the simplifier on the subterms.

We make a global setup here, as the locale one within *heap-typing-state* fails. The reason is that the pattern is not taken into account in *simproc* equality when inserted into the net. Hence multiple instances (e.g. for *globals* and *lifted-globals*) are considered a duplicate when adding them both to the net but the simplifier does not match the pattern for *globals* on a *lifted-globals* instance. In the upcoming Isabelle2024 this issue should be resolved.

    then fold (curry Int.max) (map maxidx-of-term ts) 0
    else maxidx
```

— Note that the *mk-pattern* functions serve two purposes. When adding a rule into the term net we insert Var's for the positions that we want to synthesise. The concrete program '?C' serves as index into the net and is unmodified. Note that `Utils.open_beta_norm_eta` should actually be the identity (with respect to matching) when applied to the rules.

Before querying the term-net with a concrete subgoal we also use *mk-pattern*. Here `Utils.open_beta_norm_eta` is essential to make term-net-retrieval for matching (instead of 'unification') work, as it gets rid of beta-eta artefacts in the goal that are generated during recursive application of the rules.

Chapter 25

Quickstart

JAPHETH LIM, ROHAN JACOB-RAO, DAVID GREENAWAY AND NORBERT SCHIRMER

25.1 Introduction

AutoCorres is a tool that attempts to simplify the formal verification of C programs in the Isabelle/HOL theorem prover. It allows C code to be automatically abstracted to produce a higher-level functional specification.

AutoCorres relies on the C-Parser [7] developed by Michael Norrish at NICTA. This tool takes raw C code as input and produces a translation in SIMPL [8], an imperative language written by Norbert Schirmer on top of Isabelle. AutoCorres takes this SIMPL code to produce a "monadic" specification, which is intended to be simpler to reason about in Isabelle. The composition of these two tools (AutoCorres applied after the C-Parser) can then be used to reason about C programs.

This guide is written for users of Isabelle/HOL, with some knowledge of C, to get started proving properties of C programs. Using AutoCorres in conjunction with the verification condition generator (VCG) *runs-to-vcg*, one should be able to do this without an understanding of SIMPL nor all the details of the monadic representation produced by AutoCorres. We will see how this is possible in the next chapter.

25.2 A First Proof with AutoCorres

We will now show how to use these tools to prove correctness of some very simple C functions.

25.2.1 Two simple functions: min and max

Consider the following two functions, defined in a file `minmax.c`, which (we expect) return the minimum and maximum respectively of two unsigned integers.

```
unsigned min(unsigned a, unsigned b)
{
    if (a <= b) {
        return a;
    } else {
        return b;
    }
}

unsigned max(unsigned a, unsigned b)
{
    return UINT_MAX - (
        min(UINT_MAX - a, UINT_MAX - b));
}
```

It is easy to see that `min` is correct, but perhaps less obvious why `max` is correct. AutoCorres will hopefully allow us to prove these claims without too much effort.

25.2.2 Invoking the C-parser

As mentioned earlier, AutoCorres does not handle C code directly. The first step is to apply the C-Parser by using **install-C-file** to obtain a SIMPL translation. We do this using the `install-C-file` command in Isabelle, as shown.

```
install-C-file sources/minmax.c
```

For every function in the C source file, the C-Parser generates a corresponding Isabelle definition. These definitions are placed in an Isabelle "locale", whose name matches the input filename. For our file `minmax.c`, the C-Parser will place definitions in the locale `minmax`.¹

For our purposes, we just have to remember to enter the appropriate locale before writing our proofs. This is done using the **context** keyword in Isabelle.

Let's look at the C-Parser's outputs for `min` and `max`, which are contained in the theorems `min_body_def` and `max_body_def`. These are simply definitions of the generated names `min_body` and `max_body`. We can also see here how our work is wrapped within the `minmax` context.

```
context minmax-simpl begin
```

¹The C-parser uses locales to avoid having to make certain assumptions about the behaviour of the linker, such as the concrete addresses of symbols in your program.

thm *min-body-def*

min-body \equiv

TRY

lvar-nondet-init ($\lambda upd. (min.ret'::32\ word):=_{\mathcal{L}}\ upd$);;

IF $\text{'}(min.a::32\ word) \leq \text{'}(min.b::32\ word)$ *THEN*

creturn global-exn-var'-'-update ($\lambda upd. (min.ret'::32\ word):=_{\mathcal{L}}\ upd$)
($\lambda s. s \cdot_{\mathcal{L}} (min.a::32\ word)$)

ELSE

creturn global-exn-var'-'-update ($\lambda upd. (min.ret'::32\ word):=_{\mathcal{L}}\ upd$)
($\lambda s. s \cdot_{\mathcal{L}} (min.b::32\ word)$)

FI;;

Guard DontReach {} *SKIP*

CATCH ccatchreturn global-exn-var'-'-

END

thm *max-body-def*

max-body \equiv

TRY

lvar-nondet-init ($\lambda upd. (max.ret'::32\ word):=_{\mathcal{L}}\ upd$);;

$\text{'}(max.ret'unsigned'1::32\ word) := CALL_e\ minmax.min(-\ 1 -$
 $\text{'}(max.a::32\ word),$

$-\ 1 - \text{'}(max.b::32\ word))$);;

creturn global-exn-var'-'-update ($\lambda upd. (max.ret'::32\ word):=_{\mathcal{L}}\ upd$)
($\lambda s. -\ 1 - (s \cdot_{\mathcal{L}} (max.ret'unsigned'1::32\ word))$);;

Guard DontReach {} *SKIP*

CATCH ccatchreturn global-exn-var'-'-

END

end

The definitions above show us the SIMPL generated for each of the functions; we can see that C-parser has translated **min** and **max** very literally and no detail of the C language has been omitted. For example:

- C **return** statements have been translated into exceptions which are caught at the outside of the function's body;
- *Guard* statements are used to ensure that behaviour deemed 'undefined' by the C standard does not occur. In the above functions, we see that a guard statement is emitted that ensures that program execution does not hit the end of the function, ensuring that we always return a value (as is required by all non-void functions).
- Function parameters are modelled as local variables, which are setup prior to a function being called. Return variables are also modelled as local variables, which are then read by the caller.

While a literal translation of C helps to improve confidence that the translation is sound, it does tend to make formal reasoning an arduous task.

25.2.3 Invoking AutoCorres

Now let's use AutoCorres to simplify our functions. This is done using the **autocorres** command, in a similar manner to the **install-C-file** command:

```
autocorres minmax.c
```

AutoCorres produces a definition in the **minmax** locale for each function body produced by the C parser. For example, our **min** function is defined as follows:

```
context minmax-all-corres begin
thm min'-def
```

```
min' ?a ?b ≡ if ?a ≤ ?b then ?a else ?b
```

Each function's definition is named identically to its name in C, but with a prime mark (') appended. For example, our functions **min** above was named *min'*, while the function **foo_Bar** would be named *foo-Bar'*.

AutoCorres does not require you to trust its translation is sound, but also emits a *correspondence* or *refinement* proof, as follows:

```
thm min'-ac-corres
```

```
ac-corres' (λ-. Exception ()) (lift-global-heap ∘ (λs. s) ∘ globals) True
{AssumeError, StackOverflow} Γ (λs. s ·ℒ (min.ret'::32 word))
global-exn-var'-'
((λs. s ·ℒ (min.a::32 word) = ?a') and
 (λs. s ·ℒ (min.b::32 word) = ?b') and
 (λ-. True) ∘ globals and
 (λx. abs-var ?a id ?a' ∧ abs-var ?b id ?b') ∘ lift-global-heap ∘ (λs. s) ∘
 globals)
(return (min' ?a ?b)) (Call minmax.min)
```

Informally, this theorem states that, assuming the abstract function *min'* can be proven to not fail for a particular input, then for the associated input, the concrete C SIMPL program also will not fault, will always terminate, and will have a corresponding end state to the generated abstract program.

For more technical details, see [2] and [3] or [chapter 26](#).

25.2.4 Verifying `min`

In the abstracted version of `min'`, we can see that AutoCorres has simplified away the local variable reads and writes in the C-parser translation of `min`, simplified away the exception throwing and handling code, and also simplified away the unreachable guard statement at the end of the function. In fact, `min'` has been simplified to the point that it exactly matches Isabelle's built-in function `min`:

thm `min-def`

`min ?a ?b = (if ?a ≤ ?b then ?a else ?b)`

So, verifying `min'` (and by extension, the C function `min`) should be easy:

lemma `min'-is-min`: `min' a b = min a b`
unfolding `min-def min'-def`
by `(rule refl)`

25.2.5 Verifying `max`

Now we also wish to verify that `max'` implements the built-in function `max`. `min'` was nearly too simple to bother verifying, but `max'` is a bit more complicated. Let's look at AutoCorres' output for `max`:

thm `max'-def`

`max' ?a ?b ≡ - 1 - min' (- 1 - ?a) (- 1 - ?b)`

At this point, you might still doubt that `max'` is indeed correct, so perhaps a proof is in order. The basic idea is that subtracting from `UINT_MAX` flips the ordering of unsigned ints. We can then use `min'` on the flipped numbers to compute the maximum.

The next lemma proves that subtracting from `UINT_MAX` flips the ordering. To prove it, we convert all words to `int`'s, which does not change the meaning of the statement.

lemma `n1-minus-flips-ord`:
`((a :: word32) ≤ b) = ((-1 - a) ≥ (-1 - b))`
apply `(subst word-le-def)+`
apply `(subst word-n1-ge [simplified uint-minus-simple-alt])+`

Now that our statement uses `int`, we can apply Isabelle's built-in `arith` method.

apply `arith`
done

And now for the main proof:

lemma `max'-is-max`: `max' a b = max a b`

```

unfolding max'-def min'-def max-def
using n1-minus-flips-ord
by force

```

end

In the next section, we will see how to use AutoCorres to simplify larger, more realistic C programs.

25.3 More Complex Functions with AutoCorres

In the previous section we saw how to use the C-Parser and AutoCorres to prove properties about some very simple C programs.

Real life C programs tend to be far more complex however; they read and write to local variables, have loops and use pointers to access the heap. In this section we will look at some simple programs which use loops and access the heap to show how AutoCorres can allow such constructs to be reasoned about.

25.3.1 A simple loop: `mult_by_add`

Our C function `mult_by_add` implements a multiply operation by successive additions:

```

unsigned mult_by_add(unsigned a, unsigned b)
{
    unsigned result = 0;
    while (a > 0) {
        result += b;
        a--;
    }
    return result;
}

```

We start by translating the program using the C parser and AutoCorres, and entering the generated locale `mult_by_add`.

```

install-C-file sources/mult-by-add.c
autocorres [ts-rules = nondet] mult-by-add.c

```

The C parser produces the SIMPL output as follows:

```

thm mult-by-add-body-def

mult-by-add-body ≡
TRY
  lvar-nondet-init ( $\lambda upd. (ret'::32\ word) :=_{\mathcal{L}} upd$ );;

```

```

('result::32 word) ::= SCAST(32 signed → 32) 0;;
(WHILE SCAST(32 signed → 32) 0 < '(a::32 word) DO
  '(result::32 word) ::= '(result::32 word) + '(b::32 word);;
  '(a::32 word) ::= '(a::32 word) - SCAST(32 signed → 32) 1
OD);;
creturn global-exn-var'-!-update (λupd. (ret'::32 word):=ℒ upd)
(λs. s ·ℒ (result::32 word)));;
Guard DontReach {} SKIP
CATCH ccatchreturn global-exn-var'-!-
END

```

Which is abstracted by AutoCorres to the following:

thm *mult-by-add'-def*

```

mult-by-add' ?a ?b ≡ do {
  (a, result) ← whileLoop (λ(a, result) s. 0 < a)
    (λ(a, result). return (a - 1, result + ?b))
  (?a, 0);
  return result
}

```

In this case AutoCorres has abstracted `mult_by_add` into a *monadic* form. Monads are a pattern frequently used in functional programming to represent imperative-style control-flow; an in-depth introduction to monads can be found elsewhere.

The monads used by AutoCorres in this example is a *non-deterministic state monad*; program state is implicitly passed between each statement, and results of computations may produce more than one (or possibly zero) results².

The HOL type is called specification monad: $(\prime e, \prime a, \prime s)$ *spec-monad*, where

- $\prime e$ type for exception / error results,
- $\prime r$ type of the result and
- $\prime s$ type of the state.

When $\prime e$ is instantiated with the unit type *unit*, there is an abbreviation $(\prime a, \prime s)$ *res-monad*, for *result monad*. When it is instantiated with a proper type we have an abbreviation $(\prime e, \prime a, \prime s)$ *exn-monad*, for *exception monad*.

To uniformly model results and exceptions as values the type $(\prime e, \prime a)$ *exception-or-result* is used. It is constructed as a sum type where

²Non-determinism becomes useful when modelling hardware, for example, where the exact results of the hardware cannot be determined ahead of time.

we exclude a default value from the exception type $'e$. So when $'e$ is instantiated with *unit* the type is isomorphic to the result type $'a$. Type *unit* is only inhabited by the unique unit value $()$ which is also default value. This instance is abbreviated with $'a$ *val*. For proper exceptions we instantiate $'e$ with an option type $'x$ *option*. This instance is abbreviated with $('x, 'a)$ *xval*.

Constructors and pattern matching:

- $('e, 'a)$ *exception-or-result*: *Exception e, Result v*, and pattern matching $\lambda x. \text{case } x \text{ of } \text{Exception } e \Rightarrow f \ e \mid \text{Result } v \Rightarrow g \ v$
- $'a$ *val*: *Result v*, with pattern matching $\lambda Res \ v. \ g \ v$
- $('e, 'a)$ *xval*: *Exn e, Result v*, and pattern matching $\lambda x. \text{case } x \text{ of } \text{Exn } e \Rightarrow f \ e \mid \text{Result } v \Rightarrow g \ v$

This encoding allows us to give a uniform definition of the monadic $(>>=)$ which works for the generic specification monad and thus also for its instances the result and the exception monad.

'Hoare Triples'

The bulk of *mult-by-add'* is wrapped inside the *whileLoop monad combinator*, which is really just a fancy way of describing the method used by *AutoCorres* to encode (potentially non-terminating) loops using monads.

If we want to describe the behaviour of this program, we can use Hoare logic as follows:

$$P \ s \Longrightarrow \text{mult-by-add}' \ a \ b \cdot s \ \{\!\! \{ \} \!\!\} \ Q$$

This predicate states that, assuming P holds on the initial program state, if we execute *mult-by-add'* $a \ b$, then Q will hold on the final state of the program.

There are a few details: while P has type $'s \Rightarrow \text{bool}$ (i.e., takes a state and returns true if it satisfies the precondition), Q has an additional parameter $'r \Rightarrow 's \Rightarrow \text{bool}$. The additional parameter $'r$ is the *return value* of the function; so, in our *mult-by-add'* example, it will be the result of the multiplication. Note that the precondition is not part of the 'hoare-triple' but is an ordinary Isabelle/Isar assumption on the initial state s . That way we can directly use Isabelle/Isar to decompose the precondition and can also refer to the initial state within the postcondition. The foundational constant for this hoare triple is *runs-to* which means total correctness: we have to prove that the program terminates and that there is no undefined behaviour (all guards must hold). There is also a weaker notion for partial correctness *runs-to-partial* with syntax $f \cdot s \ ?\!\! \{ \} \ Q$.

For example one useful property to prove on our program would be:

mult-by-add' $a \cdot b \cdot s \{ \lambda Res \ r \ -. \ r = a * b \}$

That is, for all possible input states, our `mult_by_add'` function returns the product of a and b .

Our proof of *mult-by-add'* could then proceed as follows:

lemma *mult-by-add-correct*:

mult-by-add' $a \cdot b \cdot s \{ \lambda Res \ r \ -. \ r = a * b \}$

Unfold abstracted definition

apply (*unfold mult-by-add'-def*)

Annotate the loop with an invariant and a measure, by adding a specialised rule to the verification condition generator.

supply *runs-to-whileLoop-res* [**where**

$I = \lambda(a', \text{result}) \ s. \ \text{result} = (a - a') * b$ **and**

$R = \text{measure}' (\lambda((a', \text{result}), s). \ a'), \ \text{runs-to-vcg}]$

Run the “verification condition generator”.

apply (*runs-to-vcg*)

Solve the program correctness goals.

apply (*simp add: field-simps*)

apply *unat-arith*

apply (*auto simp: field-simps not-less*)

done

The main tool is the proof method *runs-to-vcg*, a verification condition generator for monadic programs. It uses weakest precondition style rules which are collected in named theorems collection *runs-to-vcg*. In that collection there is no rule for *whileLoop*. The verification generator will stop there unless you specify a rule to use. This was done in the proof above by instantiating the rule *runs-to-whileLoop-res* with an invariant and a measure and by adding it to the verification condition generator via attribute *runs-to-vcg*. We finally discharge the remaining subgoals left from *runs-to-vcg* with standard proof tools of Isabelle.

In the next section, we will look at how we can use AutoCorres to verify a C program that reads and writes to the heap.

25.3.2 swap

Here, we use AutoCorres to verify a C program that reads and writes to the heap. Our C function, `swap`, swaps two words in memory:

```
void swap(unsigned *a, unsigned *b)
{
    unsigned t = *a;
```

```

    *a = *b;
    *b = t;
}

```

Again, we translate the program using the C parser and AutoCorres.

```

install-C-file sources/swap.c
autocorres [heap-abs-syntax, ts-rules = nondet] swap.c

```

Most heap operations in C programs consist of accessing a pointer. AutoCorres abstracts the global C heap by creating one heap for each type. (In our simple `swap` example, it creates only a `Word-32.word32` heap.) This makes verification easier as long as the program does not access the same memory as two different types.

There are other operations that are relevant to program verification, such as changing the type that occupies a given region of memory. AutoCorres will not abstract any functions that use these operations, so verifying them will be more complicated (but still possible).

The C parser expresses `swap` like this:

```

thm swap-body-def

```

```

swap-body ≡
TRY
  Guard C-Guard {c-guard '(a::32 word ptr)}
  ('(t::32 word) := h-val (hrs-mem 't-hrs) '(a::32 word ptr));;
  (Guard C-Guard {c-guard '(a::32 word ptr)}
   (Guard C-Guard {c-guard '(b::32 word ptr)}
    ('globals :=
     t-hrs-'update
     (hrs-mem-update
      (heap-update '(a::32 word ptr)
                   (h-val (hrs-mem 't-hrs) '(b::32 word ptr))))));;
   Guard C-Guard {c-guard '(b::32 word ptr)}
   ('globals :=
    t-hrs-'update
    (hrs-mem-update (heap-update '(b::32 word ptr) '(t::32 word))))))
CATCH ccatchreturn global-exn-var'-'
END

```

AutoCorres abstracts the function to this:

```

thm swap'-def

```

```

swap' ?a ?b ≡ do {
  guard (λs. IS-VALID(32 word) s ?a);
  guard (λs. IS-VALID(32 word) s ?b);
  t ← gets (λs. s[?a]);
  modify (λs. s[?a] := s[?b]);
  modify (λs. s[?b] := t)
}

```

There are some things to note:

The function contains guards (assertions) that the pointers `a` and `b` are valid. We need to prove that these guards never fail when verifying `swap`. Conversely, when verifying any function that calls `swap`, we need to show that the arguments are valid pointers.

We saw a monadic program in the previous section, but here the monad is actually being used to carry the program heap.

Now we prove that `swap` is correct. We use x and y to “remember” the initial values so that we can talk about them in the post-condition. The heap access syntax $s[a]$ is used to select the split heap *heap-w32* from state s at pointer a .³

```

lemma  $[[IS-VALID(32\ word)\ s\ a; s[a] = x; IS-VALID(32\ word)\ s\ b; s[b] = y]] \implies$ 
   $(swap'\ a\ b) \cdot s$ 
   $\{ \lambda\ s.\ s[a] = y \wedge s[b] = x \}$ 
apply (unfold swap'-def)
apply runs-to-vcg
apply clarsimp

```

The C parser and AutoCorres both model the C heap using functions, which takes a pointer to some object in memory. Heap updates are modelled using the functional update *fun-upd*:

```
?f(?a := ?b) = ( $\lambda x.\ if\ x = ?a\ then\ ?b\ else\ ?f\ x$ )
```

To reason about functional updates, we use the rule `fun_upd_apply`.

```

apply (simp add: fun-upd-apply)
done

```

Note that we have “only” proved that the function swaps its arguments. We have not proved that it does *not* change any other state. This is a typical *frame problem* with pointer reasoning. We can prove a more complete specification of `swap`:

```

lemma  $[[(\wedge x\ y\ s.\ P\ (s[a := x][b := y]) = P\ s);$ 
   $IS-VALID(32\ word)\ s\ a; s[a] = x; IS-VALID(32\ word)\ s\ b; s[b] = y; P\ s]]$ 
 $\implies$ 
   $(swap'\ a\ b) \cdot s$ 
   $\{ \lambda\ s.\ s[a] = y \wedge s[b] = x \wedge P\ s \}$ 
apply (unfold swap'-def)
apply runs-to-vcg
apply (clarsimp simp: fun-upd-apply)+
done

```

In other words, if predicate P does not depend on the inputs to `swap`, it will continue to hold.

Separation logic provides a more structured approach to this problem.

³For more details on the split heap model in autocorres see [section 26.21](#).

25.4 Command Options and Invocation

25.4.1 Session Structure

The supplied session structure has some peculiarities to accommodate the AFP. The AFP presents the documentation of the session that is named like the AFP-entry. This is `AutoCorres2`. This session also includes this documentation and other example application of `AutoCorres`. When you want to use `AutoCorres` for your own projects you do not have to import these examples. That's why we also supply the leaner `AutoCorres2_Main` as entry point, which we recommend as parent session for your applications.

25.4.2 C-Parser

Options for `install-C-file`,

syntax `install_C_file <filename> [<option> = value, ...]`:

- `memsafe` (default `false`): add additional guards to ensure that well-typedness of pointers
- `c_types` (default `true`): import types to UMM model
- `c_defs` (default `true`): import function to SIMPL
- `roots`: (default all functions): List of C functions that are the root functions to import
- `prune_types` (default `true`): only import those types that are actually used in the program
- `machinety`: HOL type for ghost state modelling the machine
- `gostty`: HOL type for some additional ghost state
- `skip_asm` (default `false`): Skip inline assembler

Moreover there are some Isabelle options for more feedback / tracing:

- `c_parser_feedback_level` (default 0), higher number means more tracing
- option `c_parser_verbose` (default `false`), enable for verbose messages

Multiple C Files

Command **install-C-file** only has a single C file as argument. When your project consists of several `.c` and `.h` you can register those dependencies first, with command **include-C-file**. The main C file, which is the argument to **install-C-file**, can then include all these files. If there is no such C file in your project you can create one to accomodate **install-C-file**.

Target Architecture Selection L4V_ARCH

The Environment variable `L4V_ARCH` can be used to determine the target architecture which influences the sizes of C integral types and pointer types. Supported platforms are `ARM` (default), `ARM64`, `ARM_HYP`, `RISCV64` and `X64`.

For `ARM`, the sizes are:

- 128 bits: `int128`
- 64 bits: `long long`
- 32 bits: `pointers`, `long`, `int`
- 16 bits: `short`

For `X64`, `ARM64`, `ARM_HYP`:

- 128 bits: `int128`
- 64 bits: `pointers`, `long long`, `long`
- 32 bits: `int`
- 16 bits: `short`

For `ARM64` `char` is signed.

For example to build `AutoCorres` for `ARM64`:

```
L4V_ARCH=ARM64 isabelle build -d . AutoCorres_Main
```

25.4.3 AutoCorres

Options for **init-autocorres** / **autocorres**,

syntax `autocorres [option = value, ...] <filename>`:

- **phase**: perform autocorres up to specified phase only (`L1`, `L2`, `HL`, `WA`, `IO`, `TS`)
- **scope**: space separated list of functions to perform autocorres on. (Default all).

- `scope_depth`: depth of callees to also include
- `single_threaded`: flag to disable parallel processing (e.g. to make more sense out of tracing messages)
- `no_heap_abs`: space separated list of functions that should be excluded from heap abstraction
- `in_out_parameters`: 'and' separated list of function specs e.g. `inc(y:in_out)`, cf. `../In_Out_Parameters_Ex.thy`
- `in_out_globals`: 'and' separated list of functions which modify global variables via pointers
- `skip_io_abs`: flag to disable IO abstraction
- `addressable_fields`: space separated list of paths to struct fields that should be addressable in the split heap, cf. `../open_struct.thy`
- `ignore_addressable_fields_error`: option to downgrade error to a warning
- `skip_heap_abs`: flag to disable heap abstraction (into split heap)
- `unsigned_word_abs`: space separated list of functions where unsigned words should be abstracted to *nat*.
- `unsigned_word_abs_known_functions`: assume unsigned word abstraction for function pointers
- `no_signed_word_abs`: space separated list of functions where abstraction of unsigned word to *int* should be disabled.
- `no_signed_word_abs_known_functions`: don't assume unsigned word abstraction for function pointers
- `skip_word_abs`: flag to disable word abstraction
- `ts_rules`: space separated list of rules to consider during TS phase (pure, gets, option, nondet, exit).
- `ts_force <rule-name>`: space separated list of function names to put in the specified monad (pure, gets, option, nondet, exit).
- `ts_force_known_functions`: assume function pointers live in the specified monad (pure, gets, option, nondet, exit)
- `heap_abs_syntax`: enable some additional syntax for heap accesses
- `do_polish` (default true): flag for polish phase

- `L1_opt` (RAW | PEEP (default)): level for L1 optimisation
- `L2_opt` (RAW | PEEP (default)): level for L2 optimisation
- `HL_opt` (RAW | PEEP (default)): level for HL optimisation
- `WA_opt` (RAW | PEEP (default)): level for WA optimisation
- `trace_opt`: flag to enable some tracing
- `gen_word_heaps`: flag to generate word heaps even if the program does not use them
- `keep_going`: continue despite some errors
- `lifted_globals_field_prefix`: custom prefix for split heap naming
- `lifted_globals_field_suffix`: custom suffix for split heap naming
- `function_name_prefix`: custom prefix for generated function names
- `function_name_suffix`: custom suffix for generated function names
- `no_c_termination`: flag to disable termination precondition for correspondence proofs
- `unfold_constructor_bind`: (Selectors (default) | Always | Never) to give some user level control to unfold certain "simple" binds. cf.: `../tests/proof-tests/unfold_bind_options.thy`
- `base_locale`: custom base locale for all autocorres locales

Moreover there are some Isabelle options for more feedback / tracing:

- `option verbose` (default 0), higher value means more verbosity
- `verbose_timing` (default 0), higher value means more timing messages
- `timing_threshold` (default 3), threshold in milliseconds for timing messages

Chapter 26

Overview of AutoCorres

```
theory AutoCorresInfrastructure  
imports AutoCorres  
begin
```

This theory elaborates on some of the (internal) AutoCorres infrastructure and is also supposed to act as a testbench for this infrastructure, e.g. simplifier setup.

Following the Isabelle tradition user relevant changes to AutoCorres are described in the file `../NEWS`.

26.1 Building Blocks

'AutoCorres' has the following major building blocks and contributions.

- The 'C-parser' (by Michael Norrish) takes C-Input files and parses them to 'SIMPL' (by Norbert Schirmer) programs within Isabelle/HOL:
 - C-parser: [chapter 28](#)
 - SIMPL: https://www-wjp.cs.uni-saarland.de/leute/private_homepages/nschirmer/pub/schirmer_phd.pdf
- The unified memory model (UMM) (by Harvey Tuch) models C-types as HOL-types with conversions between the typed view and the raw-byte-level view. Moreover it provides a separation logic framework.
 - UMM: <https://trustworthy.systems/publications/papers/Tuch%3Aphd.pdf>
- AutoCorres (by David Greenaway): https://trustworthy.systems/publications/nicta_full_text/8758.pdf

Some historic remarks, that might give some insight why things are as they are. The motivation for AutoCorres was the C-verification tasks coming from the sel4 Projects <https://sel4.systems>, a verified microkernel, written in C.

The project started with high level HOL-specifications, refining them to monadic functions (within HOL and Haskell) and then refining them to C-code. The nondeterministic state-monad goes back to Cook. et al http://www.cse.unsw.edu.au/~kleing/papers/Cock_KS_08.pdf. To link the C-code with the monadic functions within Isabelle / HOL the C-parser was written. The C-parser produces SIMPL programs, and SIMPL is equipped with various semantics (big and small-step) and a Hoare-logic framework including a verification condition generator. The correspondence of the C-functions represented in SIMPL and the monadic functions was manually expressed within this framework.

AutoCorres was then built after (or in parallel) to this verification effort in order to speed up the process for future projects.

While the main concepts described in the publications above are still valid, a lot of things have evolved and were extended. Especially the implementation details have changed. In this document we also give some notes on these differences. Also see `../NEWS`.

26.2 C Parser

Some remarks on the C-Parser

- Lexical and syntactical analysis is implemented using ML-Lex / ML-Yacc coming from the MLton project <http://mlton.org/>. Originally mlton was used to generate the ML files from the grammars. Meanwhile this is all integrated into Isabelle/ML.
- The C parser first generates an ML-data structure representing the program. It then does some transformations on that data structure (e.g. storing results of nested function calls into temporary variables), before translating it to SIMPL. In roughly the following steps:
 1. Generating HOL-types for the C-types.
 - The C parser performs a complete program analysis to determine the types used.
 - Defines the types and performs the UMM proofs, in particular conversions and properties to and from raw byte lists.
 2. Defining the state-space type: global variables, local variables, heap variables. The C parser does a complete program analysis to determine how global and heap variables are used to decide

whether to model them as part of the globals-record or the heap. When no 'address-of' a variable is calculated it is stored as part of the global variable record, otherwise it is stored within the heap. Global variables are more abstract to deal with compared to heap variables.

3. Defining the SIMPL procedures
4. Proving 'modifies' specifications for the procedures, i.e. frame conditions on global variables.

26.3 AutoCorres

AutoCorres abstracts the SIMPL program to a monadic HOL function in various phases, producing correspondence (a.k.a. simulation, a.k.a. refinement) theorems along the way. Note that the translation (and the correspondence theorems) might only be partial in the following sense: A phase might introduce additional guards into the code. Simulation only holds for programs that do not fail on the abstract execution. Note that non-termination is currently also modelled as failure. So simulation only holds for terminating abstract programs:

- Correspondence relation: *ac-corres*

Each phase is processed in similar stages:

- Raw translation and refinement-proof
- Optimisation of the output program, sometimes distinguished between a more lightweight "peephole" optimisation and a more heavyweight "flow" optimisation
- Define a constant for the output of the translation for that phase.

The phases are:

- From SIMPL (deep embedding of statements, shallow embedding of expressions) to L1 (shallow embedding of statements and expressions). The transformation preserves the state-space representation, and merely focuses on translating SIMPL statements to monadic functions:

- Definition of L1: `../L1Defs.thy`
- Correspondence relation: *L1corres*
- Peephole optimisation: `../L1Peephole.thy`
- Flow optimisation: `../ExceptionRewrite.thy`

- Main ML file: `../simpl_conv.ML`
- Local variable abstraction, from L1 to L2. In L2, local variables are represented as lambda abstractions. So the underlying state-space type changes, getting rid of the local variable record. As local variables are now treated as lambda abstractions, and thus names become meaningless, autocorres keeps the original names around as part of (logically redundant) name annotations within the L2 constants, e.g. *L2-gets* $(\lambda-. x) [c\text{-source-name-hint}]$. Lists of names are used, as variables might pile up in tuples. These annotations are removed in the final polishing phase of autocorres, attempting to rename the bound variables accordingly on the fly.
 - Definition of L2: `../L2Defs.thy`
 - Correspondence relation: *L2corres*
 - Exception rewriting, introducing nested exceptions: `../L2ExceptionRewrite.thy`
 - Peephole optimisation: `../L2Peephole.thy`
 - Main ML files: `../local_var_extract.ML`, `../l2_opt.ML` From now on we stay in the language L2, and also the optimisation stages are reused.
- In/Out parameter abstraction (IO). Pointer parameters are replaced by passing value parameters. This step may eliminate pointers to local variables.
 - Theory: `../In_Out_Parameters.thy`
 - Correspondence relation: *IOcorres*
 - Documentation: `In_Out_Parameters_Ex.thy`
- Heap abstraction, referred to as heap-lifting (HL). The monolithic-byte-oriented heap is abstracted to a typed-split-heap model. For that the new type *lifted-globals* is introduced. Note, that the separation logic of Tuch also attempts to give a typed view on top of the byte-level-heap. In case of nested structure types it even is capable to express the various levels of typed-heap views from bytes to individual structure fields to (nested) structures. AutoCorres takes a simpler, more pragmatic approach here and only provides a single split-heap abstraction on the level of complete types. This means there is a heap for every compound type and for every primitive type but not for nested structures. However, autocorres allows to mix between the abstractions layers (split-heap vs. byte-heap) on the granularity of functions. So you can model low-level functions like memory-allocators on the

untyped byte-heap and then still use these functions within other functions in the split-heap abstraction. Meanwhile, genuine support for a split-heap approach with addressable nested structures was added. It is described in `open_struct.thy`.

- Main theory: `../HeapLift.thy`
 - Correspondence relation: `L2Tcorres`
 - Main ML files: `../heap_lift_base.ML`, `../heap_lift.ML`
- Word abstraction (WA): (un)signed n-bit words are converted to *int* or *nat*. This conversion only affects local variable (lambda abstraction), so the underlying state-space type is maintained. When reading and storing to memory the values are converted accordingly.
 - Main theory: `../WordAbstract.thy`
 - Correspondence relation: `corresTA`
 - Main ML file: `../word_abstract.ML`
 - Type strengthening (TS), sometimes also referred to as type lifting or type specialisation: Best effort approach to simplify the structure of the monad as far as possible:
 - Pure functions
 - Reader monad, read-only state-dependant functions.
 - Option (reader) monad, in particular for potential non-terminating functions (recursion / while). Nontermination is treated as failure in autocorres and failure of guards are represented as a result of *None*
 - Nondeterministic state monad (exceptional control flow confined within function boundaries). Failure (of guards) and nontermination are represented by *Failure* as outcome.
 - Nondeterministic state monad with exit (exceptional control flow crossing function boundaries). New monad types can be registered within Isabelle / ML.
 - Main theories: `../TypeStrengthen.thy`, `../Refines_Spec.thy`
 - Correspondence relation: `refines`. Originally this was actually based on equality. As we now implement (mutually) recursive functions by a CCPO **fixed-point** instead of introducing an explicit measure parameter we changed to simulation. Equality is not `ccpo.admissible`, whereas simulation is.
 - Main ML files: `../type_strengthen.ML`, `../monad_types.ML`, `../monad_convert.ML`

- Polish. Performed as a part of type strengthening. Here remaining special and limited L2 definitions are expanded to 'ordinary' monadic functions. Also annotations of original `c` variable names are removed and bound variables are named accordingly.

26.4 AutoCorres Flow

The original AutoCorres implementation of David Greenaway was refined in several ways. In particular from a high level perspective the concepts of incremental build and parallel processing were unified:

- Parallel processing is moved to the outermost invocation of `autocorres`. All tasks are calculated respecting the dependencies of the call graph and the various `autocorres` phases, cf. `AutoCorres.parallel_autocorres`.
- Every task then invokes a distinct call to `AutoCorres.do_autocorres` exactly specifying the scope (which function clique) and which phase via the options.
- The results of an invocation are maintained in generic data, such that they are available to subsequent dependent calls.

The common parts of each phase are implemented in `AutoCorresUtil`. The last phase, Type strengthening (TS), historically played a special role and still does not make much use of `AutoCorresUtil`, but conceptually it follows the same idea:

Functions are processed in a sequence of cliques, from the bottom of the call graph to the top. Here a clique is either a single function or a group of strongly connected recursive calls. After processing of a phase the clique might get splitted due to dead code elimination. This general idea is implemented in `AutoCorresUtil.convert_and_define_cliques`.

26.4.1 General Remarks

- The main `autocorres` files, putting everything together: `../AutoCorres.thy`, `../autocorres.ML`
- There are two main approaches in a single phase to come up with an abstract program (output of the phase) and the correspondence proof to the concrete program (input of the phase):
 - Implicit synthesis of the abstract program from the concrete program by applying "intro" rules, where the abstract program is initialised with a schematic variable. Prototypical examples are the heap abstraction, word abstraction and type strengthening.

- First explicitly calculate the abstract program (fragment) within ML from the concrete program (fragment), and then perform the correspondence proof. An prototypical example is the local variable abstraction.
- The common aspects of the various stages within a single phase is (partially) generalised into library functions: `../autocorres_util.ML`

26.4.2 Links to more documentation / examples

- Pointers to local variables: `pointers_to_locals.thy`
- In-Out parameters: `In_Out_Parameters_Ex.thy`
- Addressable fields and open types: `open_struct.thy`
- Function pointers: `fnptr.thy`
- Unions: `union_ac.thy`

26.5 Overview on the Locales

The representation of local variables in SIMPL and L1 where changed from records to 'Statespaces' as implemented by `statespace` and finally to positional variables as in `locals` in `../c-parser/CLocals.thy`. This allows for an uniform representation of local variables as a function from 'nat to byte list', Typing is achieved by ML data organised in locales and bundles, cf. `../c-parser/CTranslationInfrastructure.thy`. These are also used to do the L1 and the L2 correspondence proofs. Starting from L2 on the local variables are represented as lambda bindings.

We describe the various locales (and bundles) later on with our running examples.

To support function pointers even more locales where introduced. See `fnptr.thy`.

26.6 Example Program

```
install-C-file autocorres-infrastructure-ex.c
print-theorems
thm upd-lift-simps
thm fl-ti-simps
```

The variables consist of parameters (input and output) and the local variables. Note that this is merely a ML-declaration of the scope which can be accessed via a bundle, cf. `../c-parser/CTranslationInfrastructure.thy`.

```
context includes add-variables
begin
term 'n ::= 42
end
```

Addresses of global variables or function pointers are kept in the *global-addresses* locale.

```
print-locale autocorres-infrastructure-ex-global-addresses
```

This is everything necessary to define the body of a function. All bodies are defined in that locale.

```
context autocorres-infrastructure-ex-global-addresses
  opening add-variables
begin
term add-body
thm add-body-def
end
```

The implementation locale holds the defining equation of the function in SIMPL and is closed under callees.

```
context call-add-impl
begin
thm add-impl
thm call-add-impl
end
```

In case of a clique there is a clique locale and aliases for each function.

```
print-locale even-odd-impl
print-locale even-impl
print-locale odd-impl
```

The locale importing all implementations is named like the file with suffix *-simpl*.

```
print-locale autocorres-infrastructure-ex-simpl
```

26.6.1 Incremental Build

```
autocorres [phase=L1, scope=add] autocorres-infrastructure-ex.c
autocorres [phase=L2, scope=add] autocorres-infrastructure-ex.c
autocorres [phase=HL, scope=add] autocorres-infrastructure-ex.c
autocorres [phase=WA, scope=add] autocorres-infrastructure-ex.c
autocorres [phase=TS, scope=add] autocorres-infrastructure-ex.c
```

26.6.2 All the rest

autocorres *autocorres-infrastructure-ex.c*

```
context unsigned-to-signed-impl
begin
thm unsigned-to-signed-body-def
end
context autocorres-infrastructure-ex-all-corres
begin
thm unsigned-to-signed'-def
```

The SIMPL versions produced by c-parser

```
declare [[locals-short-names]]
thm max-body-def
thm add-body-def
term add-body::((globals, locals, 32 signed word) CProof.state, unit ptr, strictc-errortype)
com
thm call-add-body-def
thm seq-assign-body-def
thm call-seq-assign-body-def
thm inc-g-body-def
thm deref-body-def
thm deref-g-body-def
thm factorial-body-def
thm call-factorial-body-def
thm odd-body-def
thm even-body-def
thm dead-f-body-def
thm dead-h-body-def
thm dead-g-body-def
```

L1 versions. Monadic with same state. Note that recursive procedures are defined with the **fixed-point** package and hence the *.simps* instead of *-def* makes more sense to look at. In this layer a first exception elimination optimisation takes places. The optimized definition has the extension "opt".

```
declare [[show-types=false]]
thm l1-max'-def
thm l1-opt-max'-def

term l1-add'::(unit, unit, (globals, locals, 32 signed word) CProof.state) exn-monad
thm l1-add'-def
thm l1-opt-add'-def

end

26.7 Simplification strategy and dealing with tuples in L2-optimization phases

Consider a congruence rule from AutoCorres

lemma

```

assumes c-eq:  $\bigwedge r s. c r s = c' r s$ 
assumes bdy-eq:  $\bigwedge r s. c' r s \Longrightarrow \text{run } (A r) s = \text{run } (A' r) s$ 
shows L2-while c A = L2-while c' A'
using c-eq bdy-eq
by (rule L2-while-cong)

```

Note that r could be a tuple and we would like to "split" it. The condition c will already be formulated with *case-prod*, e.g. $\lambda(x, y, z) s. x < y$.

When the congruence rule above is applied, variable $?c'$ has to be instantiated at some point. First the congruence rule is applied as is. Then we use *split-paired-all* to split up the r . For the example we will end up with the subgoal:

$$\bigwedge a b c s. (a < b) = ?c' (a, b, c) s$$

Mere Unification will fail here as it does not work "modulo" *case-prod*. To find the proper instantiation we developed `Tuple_Tools.tuple_inst_tac` which can be added to the simplifier as a looper. It will instantiate $?c'$ with the respective *case-prod* instance introducing a new schematic variable: $?c' = (\lambda(a, b, c). ?f a b c)$. Now the unification will kick in and do the rest of the work.

However, although an instantiation is now found, it does not have the expected effect on `body_eq`. The problem is, that the premise of the implication is not simplified as it is added to the "prems" of the simplifier so it will be $(\text{case } (a, b, c) \text{ of } (a, b, c) \Rightarrow \lambda s. a < b) s \equiv \text{True}$ and not just $a < b \equiv \text{True}$ ". The former format is unfortunately ineffective in the simplification of the while body.

Fortunately the simpset can be instructed to apply a function to the premise before it is added. So adding `Tuple_Tools.mk_simps` with `Simplifier.set_mk_simps` helps with that respect. As the simplifier descends into the term it calls the function to do "beta-reduction" of tuple application before adding the premise.

```

lemma L2-while ( $\lambda(x,y,z) s. 0 < (y::nat)$ ) ( $\lambda(x,y,z). L2\text{-seq } (L2\text{-guard } (\lambda-. 0 < y)) (\lambda-. X)) x ns
=
  L2-while ( $\lambda(x,y,z) s. 0 < y$ ) ( $\lambda(x,y,z). L2\text{-seq } (L2\text{-guard } (\lambda-. \text{True})) (\lambda-. X)) x ns
apply (tactic <
simp-tac ( @ {context}
  addloop (tuple-inst-tac, Tuple-Tools(tuple-inst-tac)
  addsimps @ {thms split-paired-all}
  |> Simplifier.add-cong @ {thm L2-seq-guard-cong}
  |> Simplifier.add-cong @ {thm L2-while-cong}
  |> Simplifier.set-mk_simps (Tuple-Tools.mk_simps)
) 1>)
done$$ 
```

Unfortunately there is still an issue. Linear arithmetic is applied as a simproc by the simplifier, e.g. $0 < n \implies \text{Suc } 0 \leq n$

Unfortunately this does not work as expected in the setup above:

```

unbundle clocals-string-embedding

```

```

lemma L2-while ( $\lambda(x,y,z) s. 0 < (y::nat)$ ) ( $\lambda(x,y,z). L2\text{-seq } (L2\text{-guard } (\lambda-. \text{Suc } 0 \leq y \wedge z = a)) (\lambda-. X)) x ns
=
  L2-while ( $\lambda(x,y,z) s. 0 < y$ ) ( $\lambda(x,y,z). L2\text{-seq } (L2\text{-guard } (\lambda-. z = a)) (\lambda-. X)) x ns
apply (tactic <
simp-tac ( @ {context}
  addloop (tuple-inst-tac, Tuple-Tools(tuple-inst-tac)
  addsimps @ {thms split-paired-all}
  |> Simplifier.add-cong @ {thm L2-seq-guard-cong}
  |> Simplifier.add-cong @ {thm L2-while-cong}
  |> Simplifier.set-mk_simps (Tuple-Tools.mk_simps)
) 1>)
oops$$ 
```

After some investigation in the interplay between the simplifier and the linear arithmetic simproc it seems that the linear arithmetic somehow ig-

nores the transformed theorem that `Tuple_Tools.mk_simps` yields. Without understanding all the details I guess the reason is the mismatch between the term in the hyps and the prop of the resulting theorem. As the simplifier adds descends into an implication $P \implies Q$ it generates a theorem from P , by also adding P to the hyps, so we have $P [P]$ as a theorem. When `Tuple_Tools.mk_simps` kicks in it only simplifies the prop not the hyps. So we end up with $a < b \equiv True [(\lambda(a, b, c) s. a < b) (a, b, c) s \equiv True]$ instead of $a < b \equiv True [a < b \equiv True]$. This seems to irritate the linear arithmetic. One solution could be to also simplify the hyps. We did not explore this path, as I would expect some issues when the hyps are eventually discharged. Nevertheless there could be a solution following that path.

We came up with a different solution. We get rid of the dependency of `Tuple_Tools.mk_simps` by using $P =simp=> Q$ to trigger simplification of P .

Note the various options to trace the simplification process.

```
declare [[linarith-trace=false]]
declare [[simp-trace=false, simp-trace-depth-limit=100]]
declare [[simp-debug=false]]
declare [[show-hyps=false]]
```

lemma

```
assumes c-eq:  $\bigwedge r s. c r s = c' r s$ 
assumes bdy-eq:  $\bigwedge r s. c' r s =simp=> run (A r) s = run (A' r) s$ 
shows  $L2\text{-while } c A = L2\text{-while } c' A'$ 
using c-eq bdy-eq by (rule L2-while-simp-cong)
```

lemma $L2\text{-while } (\lambda(x,y,z) s. 0 < (y::nat)) (\lambda(x,y,z). L2\text{-seq } (L2\text{-guard } (\lambda-. Suc 0 \leq y \wedge z = a)) (\lambda-. X)) x ns$

=
 $L2\text{-while } (\lambda(x,y,z) s. 0 < y) (\lambda(x,y,z). L2\text{-seq } (L2\text{-guard } (\lambda-. z = a)) (\lambda-. X)) x ns$

```
apply (tactic <

    |> Simplifier.add-cong @{\thm SPLIT-cong}
  ) 1)
  done

```

Finally the following setup implements a very controlled tuple esplitting on the While body.

lemma

```

assumes c-eq: c = c'
assumes bdy-eq: PROP SPLIT ( $\bigwedge r s. c' r s \implies \text{run } (A r) s = \text{run } (A' r) s$ )
shows L2-while c A = L2-while c' A'
using c-eq bdy-eq by (rule L2-while-cong-split)

```

With *SPLIT* we mark a position in the term that will trigger `Tuple_Tools.SPLIT_simproc`. By adding *SPLIT PROP ?P* \equiv *SPLIT PROP ?P* as congruence rule we prohibit the simplifier from diving into the loop body before we actually split the result variable. Note that the simplifier usually works bottom up, only congruence rules are applied top down.

lemma *L2-while* ($\lambda(x,y,(z::nat)) s. 0 < (y::nat) \wedge y=x$) ($\lambda(x,y,z). L2\text{-seq } (L2\text{-guard } (\lambda-. \text{Suc } 0 \leq y \wedge z = a)) X$) *x ns*

=
L2-while ($\lambda(x, y, z) s. 0 < y \wedge y = x$) ($\lambda(x, x, z). L2\text{-seq } (L2\text{-guard } (\lambda-. z = a)) X$) *x ns*

apply (tactic <

```

asm-full-simp-tac ( @{\context}
  addloop (tuple-inst-tac, Tuple-Tools(tuple-inst-tac)
  addsimprocs [Tuple-Tools.SPLIT_simproc, Tuple-Tools(tuple-case-simproc]
  delsimps @{\thms Product-Type.prod.case Product-Type.case-prod-conv}
  |> Simplifier.add-cong @{\thm L2-seq-guard-cong}
  |> Simplifier.add-cong @{\thm L2-while-cong-simp-split}
  |> Simplifier.add-cong @{\thm SPLIT-cong}

```

```

) 1)
done

```

26.8 Simplification of conditions (guards, loops, conditionals)

The basic peephole optimization for conditions tries to simplify "trivial" guards / conditions by propagating the information of guards / conditions to subsequent guards / conditions. It is called "peephole" optimisation (in contrast to "flow"-sensitive), because it only propagates the state independent information of guards, i.e. constraints on constant expressions or local variables, not constraints on the state itself.

To facilitate this propagation with congruence rules and simprocs, we introduce two special constants *L2-seq-gets* and *L2-seq-guard* that are introduced as intermediate step by a conversion. With this marking we can

distinguish the cases by congruence rules, without the marking both cases would be subject to a single congruence rule for *L2-seq*. (Note that the simplifier only considers the head term of a congruence rules.)

We add the congruence rules $?c = ?c' \implies L2\text{-seq-gets } ?c \ ?n \ ?A \equiv L2\text{-seq-gets } ?c' \ ?n \ ?A$ and $\llbracket ?P = ?P'; \bigwedge s. ?P' \ s \implies \text{run } (?X \ ()) \ s = \text{run } ?X' \ s \rrbracket \implies L2\text{-seq-guard } ?P \ ?X = L2\text{-seq-guard } ?P' \ (\lambda-. ?X')$. The congruence rules for the guard is a standard congruence rules that adds the gaurd as a precondition for simplifying the second statement in the sequential composition. The congruence rule for $?c = ?c' \implies L2\text{-seq-gets } ?c \ ?n \ ?A \equiv L2\text{-seq-gets } ?c' \ ?n \ ?A$ stops the simplifier from descending into the second term of the sequential composition. Instead the simproc `L2Opt.l2_marked_gets_bind_simproc` is triggered to analyse the situation. It does the following:

- If the returned value in the first statement is simple, only occurs once in second statement, or is a structure-constructor or update that is only applied to structure-selections then the value is directly propagated to the second statement and the sequential composition is removed.
- It peeks into the prems of the simplifier to see if there are already "interesting" facts collected from the congruence rules of guards / conditions. If not, it unfolds the marking and continues with the ordinary sequential composition by simplifying the second statement. "Interesting" means there is at least one premise that has impact on the new return value. E.g. if we have $x + y < (5::'a)$ in the prems, and we now we return $x + y$, than the simproc introduces a new variable r for return value, augments the context with the equation $r = x + y$ and derives the new premise $r < (5::'a)$ which is put to the premises of the simplifier as well as the simpset. Then the simplifier is called recursively on the second statement of the sequential composition with the augmented context. When it is finished it uses the rule $?f \ ?c \equiv ?g \implies L2\text{-seq-gets } ?c \ ?n \ ?f \equiv STOP \ (L2\text{-seq-gets } ?c \ ?n \ (\lambda-. ?g))$ to introduce the constant *STOP*. The congruence rule $STOP \ ?P \equiv STOP \ ?P$ prohibits the simplifier to descend down into the just simplified second statement again.

Note that this setup works around the limitation of the simplifier that does not allow us to modify the context by something like a "congruc", similar to a "simproc". Keep in mind that a congruence rule is applied top-down as the simplifier works its way down into a term, whereas a simpproc (or any other simplification rule) is applied bottom up. So a simproc / simplification rule can build on the fact that the subterms are already normalised. The simplifier makes use of this by doing some bookkeeping with "term-skeletons" to avoid resimplification of subterms. This mechanism fails short in our setup of using a

congruence rule to stop simplification of the second statement and calling the `simplproc` instead. That is why we explicitly introduce `STOP`. It will be removed after simplification by an additional traversal of the term.

It turned out that `Utils.fo_arg_resolve_tac` and other tactics like simplification can become quite slow when operating under a lot of bound variables. We introduced a `WordAbstract.thin_abs_var_tac` to remove unused premises and bound variables. It is triggered by *THIN* in the rules, e.g. $\llbracket \text{introduce-tyt-abs-fn } ?rx1.0; \ \text{THIN } (\text{corresTA } ?P \ ?rx1.0 \ ?ex \ ?L \ ?L'); \ \text{THIN } (\bigwedge r \ r'. \ \text{abs-var } r \ ?rx1.0 \ r' \implies \ \text{corresTA } (?Q \ r) \ ?rx2.0 \ ?ex \ (?R \ r) \ (?R' \ r')) \rrbracket \implies \ \text{corresTA } ?P \ ?rx2.0 \ ?ex \ (L2\text{-seq } ?L \ (\lambda r. \ L2\text{-seq } (L2\text{-guard } (?Q \ r)) \ (\lambda -. \ ?R \ r))) \ (L2\text{-seq } ?L' \ ?R')$.

26.10 Exception Rewriting

This section highlights some of the ideas to rewrite and optimise exceptions.

In SIMPL and L1 the cause for an exception is stored in the state record in field *global-exn-var'-'*. The handler then inspects the state to decide whether it is responsible or not, and either handles the exception or re-raises it. In L2 this is refined in several steps.

- The cause of the exception is moved out of the state and represented as an error result in the L2 monad.
- The check for the cause in the handler of *L2-catch* is resolved to a static nesting of *L2-try* instead. The static nesting depth is directly reflected in the depth of the sum that reflects the error value *Inl* (*Inl* ...). For local exceptions this sequence of *Inl* ends with an *Inr*, global exception (crossing function boundaries) end in an *Inl*.
- The tuple arity of intermediate bindings in statements like *L2-seq*, *L2-while* is optimised to only propagate values that are actually used later on. As a side effect of this step, unnecessary nondeterministic initialisation steps for local variables (especially the technical return variable) are removed. The initialisation becomes unnecessary if the variable is strictly assigned to before used. This is always the case for the return variable, as *return x* is translated to an assignment to the return variable followed by raising the *Return* exception.

Note that the field *global-exn-var'-'* has a special status, it is neither part of *globals* nor *locals*. In function calls it is treated like a global variable to ensure that the exception passes function boundaries. However, in the local variable abstraction of phase L2 it is treated similar to local variable and abstracted to lambda bindings.

26.12 Locales, Local-Theories, Named-Targets, Morphisms and Declarations...

We explore some of the concepts of Locales, Local-Theories, Named-Targets, Declarations etc. Besides the corresponding chapters in the Isabelle/Isar Reference Manual as well as the Isabelle/Isar Implementation Manual, the following references give a solid theoretical background:

- Local Theories: http://isabelle.in.tum.de/~haftmann/pdf/local_theory_specifications_haftmann_wenzel.pdf
- Locales: <http://www21.in.tum.de/~ballarin/publications/jar2013.pdf>
- Morphisms and Declarations: <https://www21.in.tum.de/~wenzelm/papers/context-methods.pdf>

Roughly speaking, locales provide the infrastructure to manage the dependency graph of locale declarations. When entering a locale this

dependency graph is traversed and results in a blue-print to build a local context by expanding and evaluating the locale expressions in a canonical order. The result is presented to the user as a local theory. A local theory consists of an axiomatic part (think of fixes and assumes) and a derived part, consisting of definitions and theorems within the axiomatic part.

```
locale Foo =
  fixes N::nat
  fixes M::nat
  assumes N-le-M:  $N < M$ 
```

Locale *Foo* is blue-print to build a local context. We can enter this context with **context**.

```
context Foo
begin
```

Within the context we can explore it. As an example the locale assumption becomes a theorem within the context

```
thm N-le-M
```

Within the context the axiomatic part (fixes and assumes) are often accessed implicitly. For example the fixes are presented as free Variables with the declared type fixed.

```
ML <@{assert} (@{term N} = Free (N, @{typ nat}))>
```

The locale assumptions are wrapped up in the locale predicate *Foo*, and internally become part of the hypothesis of a (local theory) theorem. Theorems derived within the local theory will all carry around this implicit hypothesis.

```
declare [[show-hyps]]
thm N-le-M
ML <@{thm N-le-M}>
thm Foo-def
```

There is also an exported version of the theorem that holds on the theory level. Here the implicit hypothesis becomes an explicit precondition.

```
thm Foo.N-le-M
```

A definition in a local theory has multiple effects. A generalised definition, where the locale fixes become explicit parameters is issued in the background theory. Moreover, an abbreviation that hides these parameters is introduced.

```
definition G-def:  $G = M + N$ 
```

```
lemma  $G = \text{Foo.G } N \ M..$ 
```

ML $\langle @\{\text{assert}\} (@\{\text{term } G\} = @\{\text{term } \text{Foo}.G \ N \ M\}) \rangle$

When working within ML we also deal with another view, the *auxiliary context* as referred to in the Isabelle documentation. On the Isar top-level we are usually only exposed to the *background theory*, e.g. $\text{Foo}.G$ and the *target context*, e.g. G .

local-setup $\langle \text{fn } lthy0 \Rightarrow$
let

val $((\text{trm}, (\text{def-name}, \text{def-thm})), lthy1) = lthy0 \ |>$
Specification.definition (*SOME* (*Binding.name* F , *NONE*, *NoSyn*))
 $\square \square$ (*Binding.empty-atts*, $@\{\text{prop } F = G + M\}$)

— $lthy1$ is now the auxiliary context. Here F aka. trm is not an abbreviation but acutally a fixed variable in that auxiliary context.

val $- = @\{\text{print}\} \text{trm}$
val $- = @\{\text{assert}\} (\text{trm} = \text{Free } (F, @\{\text{typ } \text{nat}\}))$

— Theorems within this context will have an additional hypothesis reflecting the definition equation of the F , $F \equiv \text{Foo}.F \ N \ M$. This can be explored already in *def-thm*.

val $- = \text{writeln } (\text{Thm.string-of-thm } lthy1 \ \text{def-thm})$

— One can switch between the different views / versions of a theorem by *exporting* it, either by means of an explicit export-morphism or by an export function. Out of the auxiliary context into the target context (view of the locale):

val $[\text{target-def-thm}] = \text{Proof-Context.export } lthy1 \ lthy0 \ [\text{def-thm}]$
val $- = \text{writeln } (\text{target-def-thm}: \ \hat{\ } \ \text{Thm.string-of-thm } lthy1 \ \text{target-def-thm})$
val $\text{phi-target} = \text{Proof-Context.export-morphism } lthy1 \ lthy0$
val $\text{target-def-thm}' = \text{Morphism.thm } \text{phi-target} \ \text{def-thm}$
val $- = \text{writeln } (\text{target-def-thm}': \ \hat{\ } \ \text{Thm.string-of-thm } lthy1 \ \text{target-def-thm}')$

— Out on the theory level.

val $\text{thy-lthy} = \text{Proof-Context.init-global } (\text{Proof-Context.theory-of } lthy1)$
val $[\text{theory-def-thm}] = \text{Proof-Context.export } lthy1 \ \text{thy-lthy} \ [\text{def-thm}]$
val $- = \text{writeln } (\text{theory-def-thm}: \ \hat{\ } \ \text{Thm.string-of-thm } lthy1 \ \text{theory-def-thm})$
val $\text{phi-thy} = \text{Proof-Context.export-morphism } lthy1 \ \text{thy-lthy}$
val $\text{theory-def-thm}' = \text{Morphism.thm } \text{phi-thy} \ \text{def-thm}$
val $- = \text{writeln } (\text{theory-def-thm}': \ \hat{\ } \ \text{Thm.string-of-thm } lthy1 \ \text{theory-def-thm}')$

in

lthy1

end

\rangle

Here we have the target view of the freshly defined F .

ML $\langle @\{\text{assert}\} (@\{\text{term } F\} = @\{\text{term } \text{Foo}.F \ N \ M\}) \rangle$

One notable logical difference of the view on a definition within a auxiliary context and the target context is polymorphism. Within the auxiliary context the definition is always monomorphic, maybe referring to implicitly

fixed types 'variables', or better frees. Within the target context it might be polymorphic (depending on the definition), as it is just an abbreviation for the global constant applied to the locale parameters.

The fixed view of the auxiliary context can be quite handy when continuing work with the freshly defined function, do some proofs etc. in ML.

Working with nested contexts, like fixing and assuming new stuff opening and closing them and exporting results is supported within ML by `Local_Theory.begin_nested` and `Local_Theory.end_nested`. The term might be a little bit misleading as you don't actually open an close a target but open and close a context block within the same target.

The following example illustrates this first with toplevel commands and then with ML.

```
context
  fixes K
  assumes M-le-K:  $M < K$ 
begin
lemma N-le-K:  $N < K$ 
  by (rule less-trans [OF N-le-M M-le-K])
```

Here we have the local view on the theorem within the nested context.

```
thm N-le-K
end
```

Now we have the exported view of the theorem within the target context.

```
thm N-le-K

local-setup <fn lthy0 =>
  let
    val (-, lthy) = lthy0 |> Local_Theory.begin_nested
    val ([K], lthy) = Variable.add-fixes [K] lthy
    val - = writeln (is-fixed K: ^@{make-string} (Variable.is-fixed lthy K))
    val ([M-le-K], lthy-inner) = Assumption.add-assumes [(Thm.cterm-of lthy (Syntax.read-prop
lthy  $M < K$ ))] lthy
    val thm = @{thm less-trans} OF @[{thm N-le-M}, M-le-K]
    val (([th-name,thm]), lthy) = Local_Theory.notes [((Binding.name N-le-K',[]),
[[thm], []])] lthy-inner
    val - = writeln (thm: ^ Thm.string-of-thm lthy thm)
    val lthy = lthy |> Local_Theory.end_nested
    val - = writeln (is-fixed K: ^@{make-string} (Variable.is-fixed lthy K))
    val [target-thm] = Proof_Context.export lthy-inner lthy [thm]
    val - = writeln (target-thm: ^ Thm.string-of-thm lthy target-thm)
  in
    lthy
  end
>
```

Here we have the exported view of the theorem within the target context.

```
thm N-le-K'
```

```
end
```

After a definition in a local theory the context is extended with a fixed variable for the lhs and an equation that relates it to the global definition. So everything what happens thereafter happens within that extended context.

```
ML-val <  
  val lthy = Named-Target.theory-init @{theory}  
  val ((lhs,(name, thm)), lthy) = Local-Theory.define ((binding <foo>, Mixfix.NoSyn),  
  ((Binding.empty, []), @{term 42::nat})) lthy  
  val prems = Assumption.all-prems-of lthy  
>
```

By surrounding the definition with a `Local_Theory.begin_nested` and `Local_Theory.end_nested` you can step out of the extended context again. Don't forget to export the results as well.

```
ML-val <  
  val lthy = Named-Target.theory-init @{theory} |> Local-Theory.begin-nested |>  
  snd  
  val ((lhs,(name, thm)), lthy) = Local-Theory.define ((binding <foo>, Mixfix.NoSyn),  
  ((Binding.empty, []), @{term 42::nat})) lthy  
  val lthy' = Local-Theory.end-nested lthy  
  val prems = Assumption.all-prems-of lthy'  
  val [thm'] = Proof-Context.export lthy lthy' [thm]  
>
```

26.13 Morphisms and Declarations

As we have seen before, when working with locales and local theories, we deal with different views on the same results (like theorems). The locale infrastructure takes care to provide the results in the 'expected' way by a careful naming policy for facts and (local) constants.

When maintaining results in custom (generic) context data, Isabelle provides mechanisms around the notion of a *declaration*, which comes in various flavours. In particular attached to (local) theorems / facts in the form of attributes (rule and declaration attributes) or as local theory declarations. In the case of attributes the morphism is implicit, as the theorem / facts they are attached to are already in the expected localized version. So the function can refer to these theorem / facts. In case of local theory declarations the morphism is explicitly passed as an argument to the function.

In ML, attributes are functions from `thm * Proof.context -> thm * Proof.context`, in practice presented as either a declaration attribute (modifying the context) `thm -> Proof.context -> Proof.context` or as a rule attribute (modifying the theorem) `Proof.context -> thm -> thm`. Local

theory declarations are functions, taking a morphism and modifying the `local_theory`: `Morphism.morphism -> local_theory -> local_theory`.

All these declarations are part of the context-building-infrastructure of locales and local theories. In that sense a local theory declaration can be thought of as declaration attribute attached to a dummy fact. Whenever a context is entered and the fact is processed the declarations are reevaluated on the that context. As we have seen, at each point there are three contexts simultaneously, representing the background theory, the target context and the auxiliary context. So at each point there are also three views on the data, 'viewed' via the application of the explicit or implicit morphisms.

Note that when implementing context data and tools, morphisms come in two variants. Import and export morphisms. Exporting results or data out of a context into a more general context can often be treated explicit by `Proof_Context.export` or `Proof_Context.export_morphism` or variants of those functions. This is because going out of a context is unambiguous and therefor a single morphism is enough.

Whereas when entering into a context (like entering a locale) the morphisms are internally generated and provided by the locale infrastructure. As a locale might be imported several times in different variants into the same local theory there is no unambiguous morphism. Each import provides a different morphism.

When issuing a local theory declaration via `Local_Theory.declaration` there is also two flags to define, represented as a record `{syntax: bool, pervasive: bool}`.

- A pervasive declaration is also applied to the background-theory (besides the target and auxiliary context)
- A syntax declaration is activated already in the syntax phase of the locale roundup. This means, when your context data already has to be ready to enabling parsing of new assumptions declaring a new locale you have to set the syntax flag.

Note that theorem attributes are treated like `{pervasive = false, syntax = false}`. That means that they are not evaluated on the background-theory version of the facts. This makes perfect sense for typical attributes like *simp*. The theorem is only added to the simpset within the locale. The background-theorem is not added to the simpset of the theory. Keep in mind that the background-theorem is typically an implication with the locale predicate as precondition. However, when you interpret the locale on the theory level the interpreted version of the theorem is added to the simpset of the theory, here the locale-predicate precondition is discharged.

In the following we have some examples illustrating the described behaviour.

ML <

```
structure MyData = Generic-Data (  
  type T = int;  
  val empty = 0;  
  val merge = fst;  
)  
>
```

ML <

```
val n-theory = MyData.get (Context.Theory @ {theory})  
val - = @ {assert} (n-theory = 0)  
val n-aux = MyData.get (Context.Proof @ {context})  
val - = @ {assert} (n-aux = 0)  
>
```

setup <

```
Context.theory-map (MyData.put 1)  
>
```

ML <

```
val n-theory = MyData.get (Context.Theory @ {theory})  
val - = @ {assert} (n-theory = 1)  
val n-aux = MyData.get (Context.Proof @ {context})  
val - = @ {assert} (n-aux = 1)  
>
```

context Foo

begin

ML <

```
val n-theory = MyData.get (Context.Theory @ {theory})  
val - = @ {assert} (n-theory = 1)  
val n-aux = MyData.get (Context.Proof @ {context})  
val - = @ {assert} (n-aux = 1)  
val n-target = MyData.get (Context.Proof (Local-Theory.target-of @ {context}))  
val - = @ {assert} (n-target = 1)  
>
```

Manipulating data by functions like `Context.proof_map` will only have very limited and especially temporary effect. It is applied to the auxiliary context only. When exiting the auxiliary context it will be away. Also it has no effect on the target context.

local-setup

<fn lthy =>

let

```
  val lthy = lthy |> Context.proof-map (MyData.put 2)  
  val n-aux = MyData.get (Context.Proof lthy)  
  val - = @ {assert} (n-aux = 2)  
  val n-target = MyData.get (Context.Proof (Local-Theory.target-of lthy))
```

```

    val - = @{assert} (n-target = 1)
    val n-theory = MyData.get (Context.Theory (Proof-Context.theory-of lthy))
    val - = @{assert} (n-theory = 1)

  in
    lthy
  end
>

```

You might be surprised to see that the value is already reset here. The reason is that every toplevel command resets the context and is treated like a block. Think of a `Local_Theory.begin_nested / Local_Theory.end_nested`.

```

ML <
    val n-aux = MyData.get (Context.Proof @{context})
    val - = @{assert} (n-aux = 1)
  >

```

A non pervasive declaration takes effect on the auxiliary and the target context but not the theory context.

```

local-setup <fn lthy =>
  let
    val lthy = lthy |> Local_Theory.declaration {pervasive=false, syntax=false,
    pos=here} (fn phi => MyData.put 3)
    val n-aux = MyData.get (Context.Proof lthy)
    val - = @{assert} (n-aux = 3)
    val n-target = MyData.get (Context.Proof (Local_Theory.target-of lthy))
    val - = @{assert} (n-target = 3)
    val n-theory = MyData.get (Context.Theory (Proof-Context.theory-of lthy))
    val - = @{assert} (n-theory = 1)
  in lthy end
>

```

As expected the effect is still there at this point.

```

ML <
    val n-theory = MyData.get (Context.Theory (Proof-Context.theory-of @{context}))
    val - = @{assert} (n-theory = 1)
    val n-aux = MyData.get (Context.Proof @{context})
    val - = @{assert} (n-aux = 3)
    val n-target = MyData.get (Context.Proof (Local_Theory.target-of @{context}))
    val - = @{assert} (n-target = 3)
  >
end

```

Note that the declaration is persistent in the sense that when reentering the locale it will be evaluated again. So when designing custom data and implementing declarations or attributes one has to be clear about the order of things and that they might be applied in many different situations. Using `MyData.map` instead of `MyData.put` might be handy to design robust data management.

```

context Foo
begin
ML <
  val n-theory = MyData.get (Context.Theory (Proof-Context.theory-of @{context}))
  val - = @{assert} (n-theory = 1)
  val n-aux = MyData.get (Context.Proof @{context})
  val - = @{assert} (n-aux = 3)
  val n-target = MyData.get (Context.Proof (Local-Theory.target-of @{context}))
  val - = @{assert} (n-target = 3)
  >

```

A pervasive declaration also effects the theory.

```

local-setup <fn lthy =>
  let
    val lthy = lthy |> Local-Theory.declaration {pervasive=true, syntax=false,
pos=here} (fn phi => MyData.put 4)
    val n-aux = MyData.get (Context.Proof lthy)
    val - = @{assert} (n-aux = 4)
    val n-target = MyData.get (Context.Proof (Local-Theory.target-of lthy))
    val - = @{assert} (n-target = 4)
    val n-theory = MyData.get (Context.Theory (Proof-Context.theory-of lthy))
    val - = @{assert} (n-theory = 4)
  in lthy end
  >

```

```

ML <
  val n-theory = MyData.get (Context.Theory (Proof-Context.theory-of @{context}))
  val - = @{assert} (n-theory = 4)
  val n-aux = MyData.get (Context.Proof @{context})
  val - = @{assert} (n-aux = 4)
  val n-target = MyData.get (Context.Proof (Local-Theory.target-of @{context}))
  val - = @{assert} (n-target = 4)
  >

```

end

```

ML <
  val n-theory = MyData.get (Context.Theory @{theory})
  val - = @{assert} (n-theory = 4)
  val n-aux = MyData.get (Context.Proof @{context})
  val - = @{assert} (n-aux = 4)
  >

```

26.13.1 Excuse on Proof Context vs. Local Theory.

A local theory is represented as a proof context. So a local theory is a semantic subtype of a proof context. Every local theory is a proof context but not every proof context is a local theory. In particular a local theory is a proof context that is ready to accept (local theory) definitions

(`Local_Theory.define`) and notes (`Local_Theory.note`).

The Isabelle sources try to be consistent in the naming, i.e. 'ctxt' vs 'lthy' in parameters and variables and `Proof.context` vs. `local_theory` in signatures. But as `local_theory` is only a type synonym for `Proof.context`, there is no type check for this convention. The nesting level that you get with `Local_Theory.level` is an indicator. A Level of 0 is not a proper local theory.

With `Proof_Context.init_global` you get a proof context not a local theory.

```
ML-val <
val ctxt = Proof-Context.init-global @{theory}
val level = Local-Theory.level ctxt
val is-theory = Named-Target.is-theory ctxt
val locale = Named-Target.locale-of ctxt
val bottom-locale = Named-Target.bottom-locale-of ctxt
>
```

With `Named_Target.theory_init` you get a local theory.

```
ML-val <
val lthy = Named-Target.theory-init @{theory}
val level = Local-Theory.level lthy
val is-theory = Named-Target.is-theory lthy
val locale-of = Named-Target.locale-of lthy
val bottom-locale = Named-Target.bottom-locale-of lthy
>
```

With `Locale.init` you get a proof context not a local theory.

```
ML-val <
val ctxt = Locale.init (Locale.intern @{theory} Foo) @{theory}
val level = Local-Theory.level ctxt
val is-theory = Named-Target.is-theory ctxt
val locale-of = Named-Target.locale-of ctxt
val bottom-locale = Named-Target.bottom-locale-of ctxt
>
```

With `Named_Target.init` you get a local theory.

```
ML-val <
val lthy = Named-Target.init [] (Locale.intern @{theory} Foo) @{theory}
val level = Local-Theory.level lthy
val is-theory = Named-Target.is-theory lthy
val locale-of = Named-Target.locale-of lthy
val bottom-locale = Named-Target.bottom-locale-of lthy
>
```

26.13.2 Attributes vs. Local Theory Declarations

Attributes on local facts, are not applied on the underlying theory level foundation. Only when you interpret a locale on the theory level the attributes

get activated. This corresponds to general `Local_Theory.declaration` where you have the flag `pervasive=false`.

To demonstrate this we define an artificial tracing attribute.

```

attribute-setup trace-attr =
<
  Attrib.thms >> (fn ths =>
    Thm.declaration-attribute
      (fn thm => fn context =>
        let
          val (kind, level, is-theory, locale, bottom-locale) = case context of
            Context.Proof ctxt =>
              let
                val level = Local_Theory.level ctxt
              in
                (if level = 0 then context else local-theory,
                 string-of-int level,
                 @{make-string} (Named_Target.is-theory ctxt),
                 @{make-string} (Named_Target.locale-of ctxt),
                 @{make-string} (Named_Target.bottom-locale-of ctxt))
              end
            | - => (theory, 0, true, NONE, NONE)

          val - = tracing (trace-attr ( ^ kind ^, ^ level ^, ^
            is-theory ^, ^ locale ^, ^ bottom-locale ^): ^
            Thm.string-of-thm (Context.proof-of-context) thm)
            in context end))
>

```

First we try the attribute on a theory level theorem. When you put the cursor on or after the `simp` you see the tracing output of our attribute.

```

lemma foo[trace-attr]: x = x
  by simp

```

Interestingly we see four tracing outputs. Here the outputs and my interpretation:

- `trace-attr (local-theory, 1, true, NONE, NONE): ?x = ?x` This seems to be the immediate auxiliary context of the lemma.
- `trace-attr (theory, 0, true, NONE, NONE): ?x = ?x` This is the theory level.
- `trace-attr (context, 0, false, NONE, NONE): ?x = ?x` This seems to be a theory-context that might be generated with `Proof_Context.init_global`.
- `trace-attr (local-theory, 1, true, NONE, NONE): ?x = ?x` This seems to be from reentering the original lemma context.

Now let us look at a nested context.

```
context Foo
begin
context
begin
lemma silly[trace-attr]: M = M by simp
end
end
```

As you see there is no theory level trace:

- *trace-attr (local-theory, 2, false, NONE, SOME Scratch.Foo): M = M [Foo N M]* This is the original context of the lemma.
- *trace-attr (context, 0, false, NONE, SOME Scratch.Foo): M = M [Foo N M]* This seems to be the target context but not as a local theory.
- *trace-attr (local-theory, 1, false, SOME Scratch.Foo, SOME Scratch.Foo): M = M [Foo N M]* This seems to be the target context as a local theory.
- *trace-attr (local-theory, 2, false, NONE, SOME Scratch.Foo): M = M [Foo N M]* This seems to be from reentering the original lemma context.

Let us now try an interpretation of the locale on the theory level.

```
definition NN::nat where NN = 2
definition MM::nat where MM = 3
```

```
interpretation Foo NN MM
by (unfold-locales) (simp add: NN-def MM-def)
```

We can see the trace of the activation of the attribute: *trace-attr (theory, 0, true, NONE, NONE): MM = MM*

26.14 ML Antiquotations

The notion of quote / antiquote is related to lisps quotation and quasi-quotation mechanisms or the notion of 'interpolation' that is used in the context of macros in other programming languages. In lisp, "everything is a list", in particular the program itself and you can dynamically evaluate a list. With quotation you can express that a list is meant to be plain data and should not be immediately evaluated. With quasi-quotation you can

build data which inside uses a lisp-expression that evaluates / expands to some data that is inserted at that point.

This is a first intuition to understand ML antiquotations in Isabelle/ML. An ML antiquotation is something embedded into the Isabelle/ML program text, that is not itself plain ML, but something that evaluates to a piece of ML text that is inserted in that position. A prominent example is the term antiquotation, which transforms a logical term (presented in the inner-syntax) of the logic, to the ML representation of that term. `term`

```
ML-val <
term <x + y>
>
```

The expansion takes place during compile time of the piece of Isabelle/ML. To be more precise it is expanded already during lexing of Isabelle/ML. This is important to keep in mind when writing your own antiquotations. The context you can refer to during the expansion of the antiquotation is the context you have during the lexing phase. This design decision facilitates robustness and predictability of the resulting ML code. Note that the expanded ML-code itself might of course be dynamically used later on in various contexts, but it is always the same code.

The main interface to write your own ML antiquotations is `ML_Antiquotation`. The more low-level (and more flexible) interface it is based on is `ML_Context.add_antiquotation`. The interface in `ML_Antiquotation` distinguishes the antiquotations into the variants *inline*, *value* and *special-form*.

The *inline* variant is the closest to the intuition of macro expansion. The inline-antiquotation yields a piece of ML-text that is literally inserted at the position of the antiquotation. The term antiquotation is an example of this. `\<^term>\<open>x + y\<close>`. It is implemented with `ML_Antiquotation.inline_embedded`.

¹

For the *value* variant the intuition is that the expanded antiquotation is immediately evaluated in the compile time context and the resulting value is what is inserted at the position of the antiquotation. An example is the `cterm` antiquotation, e.g. `@{cterm "a = b"}`.

Following the static nature of antiquotations this abstract value is produced statically during compile time and is bound to some value as in *val x*

¹Note that there is also a variant without the 'embedded' suffix `ML_Antiquotation.inline`. What is the difference? According to a mail thread <https://lists.cam.ac.uk/mailman/htdig/cl-isabelle-users/2021-October/msg00023.html> the 'embedded' is a hint to Isabelle that antiquotation expects its argument as an 'embedded language' enclosed by a cartouche. This can nowadays be considered as the canonical way. Historically, Isabelle first distinguished between the outer-syntax (e.g. Isar or plain ML as Meta-Language) and the inner-syntax of the object logic like HOL or FOL. Meanwhile Isabelle embraces a lot of different languages that in some cases can even be nested, and the languages can be dynamically extended by declaring new commands or antiquotations.

= ...*compile-time-context*..., and then this value x is what appears in the expanded ML text. So to implement such an antiquotation means to provide two main ingredients: the code for the value binding (referred to as environment) and the code to reference that value (referred to as body). This is what the interface `ML_Antiquotation.declaration` offers. The argument `Proof.context -> string * string` is the central point. The pair of strings denotes the ML-text for the environment and the body respectively. See for example the theorem antiquotation: `@{thm refl}`. This can also be considered a *value* antiquotation, albeit being implemented by the more low-level interface.

Digging even deeper into `ML_Context.add_antiquotation` the `ML_Context.decl` also refers to a pair of ML-code, denoting an environment and the body, but here presented as `ML_Lex.token list` not as a string. This interface gives a lot of flexibility into the design of antiquotations. A notable example is the 'instantiate'-antiquotation. e.g:

```
ML-val <
fun foo t =
  instantiate <'a =typ <nat> and a =term <s::nat> and b = t in
    prop <a + b = b + a> for a b::<'a::plus>>
  >
```

Note the nesting of antiquotations in that example. The 'environment-part' here consists of all the right hand sides of the instantiations as well as the proposition. The 'body-part' is an ML-expression that instantiates the proposition with the terms. The body part cannot be immediately evaluated during compile time as the value of parameter t of the function is not yet known. So the result is an ML-expression that references t among the right and sides of the instantiations that are evaluated at compile time.

The special-form antiquotation packs the text in a function `think`, e.g. `\<^try>\<open>I\<close>`.

26.15 Markup and Reports

Isabelle provides a rich set of markup to display information in Isabelle/jEdit. Markup can either be directly attached to a string, or an existing source text can be decorated by sending *reports* to PIDE. An example for direct markup is the printing of terms, e.g.:

```
ML <
val str = Syntax.string-of-term @<context> @<term a + b>
  >
```

You can make the markup visible by sending it to an output function, e.g.

```
ML <
```

```
tracing str
>
```

The markup is itself encoded in the string by the format `YXML`. The plain information (without markup) can be extracted:

```
ML-val <
YXML.content-of str
>
```

The markup can be expanded to the `XML.tree` by `YXML.parse`

```
ML-val <
YXML.parse str
>
```

To build up markup you can use `Markup`. The type for markup is a pair of element name and a list of properties. A property `Properties.T` is a key value pair which are both strings. First you build up your markup by using the various functions supplied in `Markup`, then you attach it to a string via `Markup.markup`.

```
ML-val <
val m = Markup.url http:\\www.isabelle.in.tum.de
val decorated = Markup.markup m attach url to this string
val xml = YXML.parse decorated
>
```

With `Position.report` you can add markup to a given position, e.g. here we add the warning-twigglies and an url:

```
ML-val <
val pos = Position.range-position (Position.range (here, here))
val w = Markup.warning
val u = Markup.url http:\\www.isabelle.in.tum.de
val - = Position.report pos w
val - = Position.report pos u
>
```

The standard message channels `error`, `warning` and `tracing` scan the string for position information and automatically markup the position.

```
ML-val <
val this-spot = here (* wiggly line *)
val msg = Look here: ^ Position.here this-spot
val - = warning msg
>
```

There are some fine points regarding the command region where the message is issued. By default markup is only shown in the actual command region.

```
ML <
val this-spot-is-not-marked = here (* no wiggly line *)
```

```
val msg1 = Look here: ^ Position.here this-spot-is-not-marked
>
```

We do not get the wiggly lines in the **ML** above, instead the **ML-val**

```
ML-val <
val - = warning msg1
>
```

We can put markup to a previous command if we first save the command position of the first command, and temporary use this in the second command when issuing the message.

```
ML <
val command-thread-position = Position.thread-data ();
val this-spot-is-marked = here (* wiggly line *)
val msg2 = Look here: ^ Position.here this-spot-is-marked
>
```

```
ML-val <
val - = Position.setmp-thread-data command-thread-position warning msg2
>
```

To inspect the markup attached to the source you can use the panel Sidekick and select the language "isabelle-markup" When you hover over an entity in the upper half of the panel you see the attached markup in the lower half of the panel.

Reports are also used in autocorres **Feedback** to provide warning and error markup for C programs.

An illustrative example for custom markup and reports can be seen in the document antiquotation for rail diagrams: is `$ISABELLE_HOME/src/Pure/Tools/rail.ML`. It is used extensively in the Isabelle documentation, watch out for `\<^rail>\<open>\<close>` e.g. in `$ISABELLE_HOME/src/Doc/Datatypes/Datatypes.thy`

26.16 Term Synthesize via Intro Rules

A repeated task in the various AutoCorres phases is to synthesize a typically more abstract monadic function (output) from a given monadic function (input) together with a simulation theorem that connects both versions of the function. One strategy is to formulate introduction rules for the correspondence relation for the different language constructs and then recursively apply those rules guided by the constructs in the "input" function, and as a side effect of the rule application to synthesize the "output" function. Examples are, heap abstraction, word abstraction, exception rewriting (as described above) and type strengthening. Currently there is not (yet) an uniform implementation of this strategy, but the different instances are converging.

Currently the most recent incarnation is the setup for type strengthening to perform the *refines* proofs:

- A term net is used for efficient lookup of potentially matching rules. It is indexed by the input function as well as the desired result relation.
- Splitting of tuples in rules is automatically performed to match the current term.
- Priorities of rules are specified to guarantee that the most specific rules are tried first
- A cache is used both for positive and negative proof attempts. As there might be multiple applicable rules when decomposing the input function, partial results might already be proven or have failed. Using a cache helps to prune repeated subproof attempts.

The setup for this phase can be found in `../Refines_Spec.thy`. It employs **synthesize-rules**, as defined in `../lib/ml-helpers/Synthesize.thy`. This command can be seen as generalisation of **named-theorems**, with support for the kind of features just sketched.

For a set of **synthesize-rules** you can generate patterns to support indexing of rules via subterms: **add-synthesize-pattern**.

With **print-synthesize-rules** you can inspect the set:

print-synthesize-rules *pure*

You can also supply an term to select the matching rules:

print-synthesize-rules *pure* $\langle \text{Trueprop } (\text{refines-spec } (L2\text{-try } f) - (\text{return } ?f') - (\text{rel-prod } \text{rel-liftE } (=)))) \rangle$

Rules are added via attribute *synthesize-rule*, where you can also specify the rule sets the priority and whether to split some variables. In order to preserve the theorem name for debugging purposes you should apply that attribute in a separate **lemmas** and not directly in the original **lemma**

The main tactic to drive application of those rules is `CT.cache_deepen_tac`. This tactic has type `context_tactic` and supports implementing a cache within the `Proof.context`. The user provides a cache and a single-step tactic that is recursively tried on the emerging subgoals.

The interface of the cache is captured in record `CT.ctx_cache`:

- **#lookup**: `CT.ctx_cache -> Proof.context -> cterm -> int -> context_tactic` The lookup function gets the goal presented as a `cterm` and returns a subgoal tactic. A cache miss is implemented by `K CT.no_tac`.

- **#insert:** `CT.ctx_cache -> (Timing.timing * int * int) -> thm -> Proof.context -> Proof.context` The insert functions gets timing information tupled with the total number of alternatives and the current alternative as input together with the just proven subgoal. It can use that information to decide whether to really extend the cache or to ignore the result.
- **#propagate:** `CT.ctx_cache -> Proof.context -> Proof.context -> Proof.context` To propagate the cache throughout backtracking the propagate function is supplied. It gets the current context and the old context as argument and can propagate the cache from the current context to the old one (to which it backtracks).

The cache used for the type strengthening phase is implemented in `Monad_Convert.sim_nondet`. It is based on `Synthesize_Rules.gen_cond_cache`. It uses a term net to index the cached results and only adds rules for compound statements like *L2-seq*, not for atomic ones. The idea here is that proving simulation for an atomic statement is just a single rule application and is thus not worth to be cached.

Failed proof attempts are represented by $FALSE \implies PROP ?P$ instantiated with the failed subgoal. This is how they are presented to the cache and can be stored. When a cache lookup is performed and the cache results in such an instance of $FALSE \implies PROP ?P$ which matches the current subgoal the proof attempt will be immediately aborted at that depth and potential alternative proof steps 'higher up' (smaller depth) may get explored.

Next we illustrate the approach with a small example.

lemma *refines-liftE-nondet*: *refines (liftE f) f s s (rel-prod rel-liftE (=))*
by (*auto simp add: refines-def-old reaches-liftE*)

lemma *refines-L2-unknown*:

shows *refines (L2-unknown ns) (L2-VARS (select UNIV) ns) s s (rel-prod rel-liftE (=))*

by (*rule Refines-Spec.refines-L2-unknown-nondet*)

lemmas *refines-spec-monad-rules* =

refines-L2-seq-nondet [*simplified THIN-def*]

refines-L2-gets-nondet

refines-L2-unknown

lemmas *refines-option-monad-rules* =

refines-L2-seq-option [*simplified THIN-def*]

refines-L2-gets-option

schematic-goal $\langle \text{refines } (L2\text{-seq } (L2\text{-gets } (\lambda\cdot. n::\text{nat}) [])) (\lambda n. L2\text{-gets } (\lambda\cdot. n + m) []) \rangle$ $(?f'::(?'c, 'a) \text{ res-monad}) ?s ?s ?R$

apply (*rule refines-spec-monad-rules*)
prefer 2

— Note that `CT.cache_deepen_tac` follows the convention of tactics to solve subgoals from the back. So the second subgoal is solved first.

apply (*rule refines-spec-monad-rules*)
apply (*rule refines-spec-monad-rules*)
done

First we define the single-step tactics, which just try some rules.

ML \langle

```
fun get-nondet-tacs goal = @{thms refines-spec-monad-rules}
  |> map (fn thm => (Utils.guess-binding-of-thm @ {context} thm, thm))
  |> CT.binding-resolve-tac
```

```
fun get-option-tacs goal = @{thms refines-option-monad-rules}
  |> map (fn thm => (Utils.guess-binding-of-thm @ {context} thm, thm))
  |> CT.binding-resolve-tac
```

```
fun get-all-tacs goal = get-option-tacs goal @ get-nondet-tacs goal
  >
```

Now we define a simple cache which stores all emerging subgoals in a list and tries to resolve with those subgoals on a lookup.

ML \langle

```
structure List-Cache = Proof-Data (
  type T = thm list
  val init = K [])
```

```
val list-cache:CT.ctx-cache = {
  lookup = fn ctxt => fn goal =>
    let
      val - = tracing (lookup: ^ Syntax.string-of-term ctxt (Thm.term-of goal))
    in
      CT.resolve-tac (List-Cache.get ctxt)
    end,
  insert = fn timing => fn thm => fn ctxt =>
    let
      val thm' = thm |> Thm.forall-elim-vars ((Thm.maxidx-of thm) + 1) |>
zero-var-indexes
      val - = tracing (insert: ^ Thm.string-of-thm ctxt thm')
    in
      ctxt |> List-Cache.map (cons thm')
    end,
  propagate = fn current => fn old => current
}
```

>

We only try nondet-rules, so we end up in the nondet monad.

schematic-goal

```
⟨refines ( L2-seq (L2-gets (λ-. n::nat) []) (λn. L2-gets (λ-. n + m) []))
  (?!f'::(!'c, 'a) res-monad) ?s ?s ?R⟩
apply (tactic ⟨
  Context-Tactic.NO-CONTEXT-TACTIC @{context} (
  CT.cache-deepen-tac (K 1) list-cache get-nondet-tacs 1
  )⟩)
done
```

schematic-goal

```
⟨refines ( L2-seq (L2-gets (λ-. n::nat) []) (λn. L2-gets (λ-. n + m) [])) (?!f'::(!'c,
'a) res-monad) ?s ?s ?R⟩
thm refines-option-monad-rules
apply (rule refines-option-monad-rules)
apply (rule refines-option-monad-rules)
apply (rule refines-option-monad-rules)
done
```

We only try the option-rules, so we end up in the option monad.

schematic-goal

```
⟨refines ( L2-seq (L2-gets (λ-. n::nat) []) (λn. L2-gets (λ-. n + m) [])) (?!f'::(!'c,
'a) res-monad) ?s ?s ?R⟩
apply (tactic ⟨
  Context-Tactic.NO-CONTEXT-TACTIC @{context} (
  CT.cache-deepen-tac (K 1) list-cache get-option-tacs 1
  )⟩)
done
```

No we try both the option-rules and the nondet-rules. As the option rules come first we end up in the option monad

schematic-goal

```
⟨refines ( L2-seq (L2-gets (λ-. n::nat) []) (λn. L2-gets (λ-. n + m) [])) (?!f'::(!'c,
'a) res-monad) ?s ?s ?R⟩
apply (tactic ⟨
  Context-Tactic.NO-CONTEXT-TACTIC @{context} (
  CT.cache-deepen-tac (K 1) list-cache get-all-tacs 1
  )⟩)
done
```

By including a *L2-unknown* in the example we have to end up in the nondet monad, as it cannot be handled in the option monad. Note the difference in the outcome of the first and second proof attempt. In the first one we only provide the nondet-rules in the second one we also provide the option-rules. This results in a different "translation" of the first *L2-gets*.

schematic-goal

```

⟨refines ( L2-seq (L2-gets (λ-. n::nat) [])) (λn. L2-unknown []) ( ?f'::( ?'c, 'a)
res-monad) ?s ?s ?R⟩
  apply (tactic ⟨
    Context-Tactic.NO-CONTEXT-TACTIC @{context} (
      CT.cache-deepen-tac (K 1) list-cache get-all-tacs 1
    )⟩)
done

```

schematic-goal

```

⟨refines ( L2-seq (L2-gets (λ-. n::nat) [])) (λn. L2-unknown []) ( ?f'::( ?'c, 'a) res-monad)
?s ?s ?R⟩
  apply (tactic ⟨
    Context-Tactic.NO-CONTEXT-TACTIC @{context} (
      CT.cache-deepen-tac (K 1) list-cache get-nondet-tacs 1
    )⟩)
done

```

end

26.17 Pointers to Local Variables

```

theory pointers-to-locals imports AutoCorres
begin

```

```

install-C-file pointers-to-locals.c

```

```

init-autocorres [addressable-fields = pair.first buffer.buf 32 word[3]]pointers-to-locals.c

```

```

autocorres [no-heap-abs = inc-untyp]pointers-to-locals.c

```

This story began with the desire to support "pointers to local variables". The idea to support "pointers to local variables" might be quite fearful as it covers lots of use cases. When trying to literally support pointers to local variables (uniform with heap pointers) one has to answer questions about the memory layout of heap and stack, how to ensure that those regions are disjoint, what happens if we run out of stack space, how do we make sure that there is no dangling pointers to a stack-frame that is already popped from the stack etc.

So let us make a step back and ask ourselves for which C-idiomatic use cases are pointers to local variables actually used. C does only support call-by-value. So pointers are sometimes used to model call-by-reference semantics, for input as well as output parameters. Especially, the use case of an additional output parameter (besides the regular return value) is often implemented as a pointer parameter. An alternative might be to return a tuple encoded as a structure instead. But as there are no ad hoc tuples in C, this requires the boilerplate to define an auxiliary structure type. So typically a pointer parameter is used instead.

Here an example of a integer addition with overflow check. The return

value is used for the status, the actual result is returned as a pointer parameter.

```
int add_check(int* result, int a, int b)
{
    *result = a + b;
    if(a > 0 && b > 0 && *result < 0)
        return -1;
    if(a < 0 && b < 0 && *result > 0)
        return -1;
    return 0;
}
```

A call to the function could be the following with a local variable for the result.

```
int res, status;
status = add_check(&res, 2, 3)
```

Here `res` is an output parameter. If C would support tuples we might have code like:

```
int add_check(int a, int b)
{
    int result = a + b;
    if(a > 0 && b > 0 && *result < 0)
        return (-1, result);
    if(a < 0 && b < 0 && *result > 0)
        return (-1, result);
    return (0, result);
}
```

```
int res, status;

(status, res) = add_check(2, 3)
```

Another use case is to have in input / output parameter implemented by a pointer parameter.

```
void inc(int *a)
{
    (*a)++;
}

int x = 42;
inc(&x);
```

This could be also modelled as explicit input and output:

```
int inc(int a)
{
    return (a++);
}
```

```
int x = 42;
x = inc(x);
```

So one general idea is to model those kind of pointer-parameters as explicit input / output parameters. From a pattern like:

```
int f(int *p1, ..., int * p_n, int a1, ..., int a_m) {
    ... (*p1) ...
    ... (*p_i) ...
    return res;
}
```

```
r = f(q1,..., q_n, b1, ..., b_m)
```

We make

```
(int * int ... * int) f(int p1, ..., int p_n, int a1, ..., int
a_m) {
    ... p1 ...
    ... p_i ...
    return (res, p1, ... p_n);
}
```

```
(r, q1, ..., q_n) = f(q1,..., q_n, b1, ..., b_m)
```

In which cases is such a model faithful? Different behaviours might occur, when pointer-parameters are aliased. Moreover, the translation scheme only works out if the body of the function only uses the dereferenced pointer variables, i.e. `*p_i` to obtain the value or perform an update, and does not actually use the literal address value stored in the variable. E.g. it does not make things like `p1 = p2` or stores the pointer value in some global data structure. All examples we have seen so far are benign with this respect, as there was only one pointer-variable involved, and we only used it to dereference it.

What about this swap function:

```
void swap1(int* p, int* q) {
    int tmp = *p;
```

```

    *p = *q;
    *q = tmp;
}

int a = 1; int b = 2;
swap1(&a, &b);
/* a = 2, b = 1 */

```

```

(int * int) swap2(int p, int q) {
    int tmp = p;
    p = q;
    q = tmp;
    return (p, q);
}

```

```

int a = 1; int b = 2;
(a, b) = swap2(a, b);
/* a = 2, b = 1 */

```

These two swap functions behave the same, even if the parameters would alias. But in general aliasing is problematic.

```

void inc_both1(int* p, int* q) {
    *p = *p + 1;
    *q = *q + 1;
}

```

```

int x = 2;
void inc_both1(&x, &x);

/* x = 4 */

```

```

(int * int) inc_both2(int p, int q) {
    p = p + 1;
    q = q + 1;
    return (p, q);
}

```

```

int x = 2;
(x, x) = inc_both2(&x, &x);

/* x = 3 */

```

Whats the relevant difference between the increment and the swap example? In the swap example, we never read from a pointer-parameter after any pointer-parameter was assigned to. So an update within the function might not alter the values we read via any pointer-parameter.

26.17.1 Design choices

C does not distinguish pointers to local variables from heap pointers they are all the same. E.g. the increment functions above could be applied to a heap location as well as a stack location. Moreover, in the context of systems programming it is common that low-level code explicitly deals with heap-layout and pointer values and "tricks" like storing some flags as bits in the pointer values themselves are often used. That is why we aim for an uniform model for stack and heap pointers and don't want to impose assumptions on the layout.

Whenever a function creates a pointer to a local variable, we model it as part of the heap. Core ideas:

- As part of ordinary heap-typing, we track free stack locations by a distinguished C type *stack-byte*. All addresses with that type are considered free stack location.
- Additionally to the typing information with *stack-byte* (that denotes free stack space) We have a fixed set of addresses \mathcal{S} that describe all the stack space (free and allocated). Note that the set \mathcal{S} does not depend on the state. The dynamic aspects are modelled within the heap typing.
- As prelude in a function that needs pointers to local variables we allocate the variable in the heap, by non-deterministically retyping a region of free stack space that fits: We retype from *stack-byte* to the type we allocate.
- All accesses / updates to the variable within the function are modelled indirectly via the pointer
- As postlude of the function we again retype the stack space as free.

Observations:

- Ordinary C functions, that do not have an AUX-UPDATE on the heap-type also do not mess around with the stack as they do not change heap-typing. So stack-space is preserved when calling a function.
- Prelude / postlude ensures that the stack typing is the same after a function call to a function that has pointers to local variables.

Stack Allocation

The central definition for stack allocation is *stack-allocs* describing the set of possible pointers and modified heap type descriptions:

$$(p, d') \in \text{stack-allocs } n \ \mathcal{S} \ \text{TYPE}('a) \ d$$

thm *stack-allocs-def*

After such an allocation we know that:

- Pointer p is a root pointer with the expected type in the new heap type description d' .
- The allocated addresses are within set \mathcal{S} .
- The new heap typing d' is obtained from the original heap typing d by retyping addresses of *stack-byte* to the type of the pointer p . The address of pointer p denotes the start the retyped region. The parameter n can be used to allocate a consecutive range of pointers in one step.

Stack allocation might fail in the sense that the resulting set of *stack-allocs* can be empty. In *Simpl* we then fail in the terminal fault state reporting *StackOverflow*. In the autocorres monad we currently have decided to ignore possible stack overflows. We simply assume that stack allocation succeeds and does not return an empty set.

Stack Release

The counter part to the stack allocation above is *stack-releases* $n \ p \ d'$.

thm *stack-releases-def*

There is no non-determinism here. It is a plain function retyping back to *stack-byte*.

Stack discipline

We encapsulate the stacking discipline of allocation / release in some functions in the various layers.

Simpl In *Simpl* we have the command *With-Fresh-Stack-Ptr* $n \ \text{init } c$ where

- n denotes the number of consecutive pointers we want to allocate, typically $1::'a$. This number was introduced to allocate local arrays and obtain pointers to the elements. However, it turns out that allocating an array pointer $('a['b]) \ ptr$ instead is sufficient. Hence the parameter is actually always $1::'a$.

- *init s* returns a set of initial values from which we non-deterministically choose one. In case the addressed local variable is a function parameter this is a singleton set containing the value of the argument. In case of an ordinary local variable this is either the the universal set of all possible values (if uninitialized) or a singleton set of the initialisation value.
- *c* expects a fresh pointer *p* and then yields a Simpl command of the body.

The idea is simple, we first allocate a pointer *p* with *stack-allocs*, then initialise the fresh heap location according to *init* then execute the body *c p* and finally release the stack pointer again.

thm *globals.With-Fresh-Stack-Ptr-def*
term *stack-heap-state.With-Fresh-Stack-Ptr*

A central role of the definition is the *DynCom* statements, which is the means of Simpl to bind certain execution points and provide state dependent commands. As the body of a *DynCom* always depends on the complete state (and not such a thing like the pointer *p*) we use the function *allocated-ptrs* calculate the fresh pointer from the typing information.

thm *allocated-ptrs-def*
thm *stack-allocs-allocated-ptrs*

Note that *spec-monad.Spec* might fail if the resulting set is empty, which is exposed to the failure *StackOverflow* of the command.

L1 / L2 In both L1 and L2 we use *globals.with-fresh-stack-ptr n init f*, where *n* as well as *init* are just the same as in Simpl and *f* is a monadic computation depending on the fresh pointer *p*.

term *globals.with-fresh-stack-ptr*
thm *globals.with-fresh-stack-ptr-def*
term *stack-heap-state.with-fresh-stack-ptr*

In contrast to Simpl we assume that stack allocation succeeds by using *assume-result-and-state*.

HL / Split Heap

In the split heap model there is no singleton heap anymore. Hence we introduce a family of functions depending on the type that is allocated.

term *heap-w32.with-fresh-stack-ptr*
thm *heap-w32.with-fresh-stack-ptr-def*
term *heap-w32.guard-with-fresh-stack-ptr*
thm *heap-w32.guard-with-fresh-stack-ptr-def*

```

term heap-w32.assume-with-fresh-stack-ptr
thm heap-w32.assume-with-fresh-stack-ptr-def
term typ-heap-typing.with-fresh-stack-ptr
term typ-heap-typing.guard-with-fresh-stack-ptr
term typ-heap-typing.assume-with-fresh-stack-ptr

```

While stack allocation remains the same upon stack release some more work has to be done in order to make the simulation work.

In the monolithic heap the stack release of a pointer p immediately results in $\text{plift}(h, \text{stack-releases } n \ p \ d') \ p = \text{None}$. So the simulation demands $\text{the-default ZERO}'a) (\text{plift}(h, \text{stack-releases } n \ p \ d') \ p) = \text{zero}$.²

So to simulate this in the split heap we explicitly zero out the memory. Moreover, for the simulation to work we have to argue that the stack release did not mess up with any of the other split heaps. This argument can be given if know that pointer p is still a valid root pointer before we do the release. As we know that p is a valid root pointer immediately after the allocation we have to establish that this is still true at stack release. Most C function do not alter the heap typing at all. So it can easily be shown that $f \cdot s \ \text{?}\{\lambda r. \text{unchanged-typing-on } \mathcal{S} \ s \ \}\} holds and thus that p is still a valid root pointer after executing f . In case we cannot automatically proof the preservation of typing information, we enforce that p is still a valid root pointer by inserting a guard. So for code that changes the heap typing in more involved ways the argument is left for the user to prove.$

Value parameters aka. In-Out parameters

Now that we have proper pointers to local variables there is room for further abstractions, motivated by the prominent use cases described in the beginning. Those use cases suggest that in a lot of cases one can completely get rid of stack allocation / release by introducing value parameters: Instead of just passing a pointer value into the function, one passes in the actual (dereferenced) value and tuples the return value of the function with the final (dereferenced) value of that parameter.

It turns out that the core transformation here is not so much about pointers to local variables but more on transforming functions from passing in a pointer parameter to another function value parameters. This part of the transformation is independent of the question heap pointer vs. stack pointer. After this transformation is done for the body of a function which allocates a stack pointer, the actual address of the stack pointer becomes meaningless as it is only used in "dereferenced form". So we can remove the stack allocation / stack release and replace it by an ordinary local variable.

See `In_Out_Parameters_Ex.thy` for more information.

26.18.1 Overview

We introduce a new phase in AutoCorres to replace pointer parameters by *in/out parameters*: Instead of passing a pointer into a function we pass the initial value of the pointer (by dereferencing the pointer) into the function and return the value at the end of the function as additional output. E.g. a function `void inc(unsigned *n)` becomes `unsigned inc(unsigned n)`. The initial motivation for this phase was to get rid of explicit pointers to local variables and replace them by ordinary values instead. This conversion has two main aspects:

- Function signatures may change: pointer parameters become value parameters and the function may return the value of the pointer at the end as an additional return value (tupled with the ordinary return value). Functions with side effects on the heap may become pure functions on values by this transformation.
- As a result of the first transformation, pointers to local variables may be eliminated and be replaced by bound variables. This means that *stack-heap-state.with-fresh-stack-ptr* disappears.

The new phase is called *IO* and is placed between L2 and HL. This means local variables are already represented as bound variables in L2 and we still operate on a monolithic heap.

26.18.2 Building Blocks

What ingredients do we need for the abstraction relation in the refinement proof?

- Heaps: As we eliminate pointers, the original function manipulates the heap more often than the resulting function. So we need a notion to relate the heap states and keep track of the relevant pointers. As the stack of local variable pointers is also modelled in the heap the stack free locations are also of interest. The heaps of the original and the resulting program may differ in these locations. The heap value of a stack free location should be irrelevant for the program.

- Function signatures: The function signature changes, pointer parameters become ordinary values, the return value is tupled with output parameters.

In the following we refer to the original state (containing the heap) as s and the resulting / abstract state as t . As I first idea we want to relate states s and t such that the heaps are the same except for some pointers we want to eliminate and the stack free locations. It would be natural to describe this as a relation. However, it turns out that dealing with relations within the refinement proof are hard to make admissible in order to support recursive functions. Having a abstraction / lifting function (instead of a relation) from s to t makes admissibility straightforward.

As a prerequisite we encourage the reader to consider the documentation about pointers to local variables: `pointers_to_locals.thy`

context *heap-state*
begin

frame

We want to express that certain portions of the heap (typing and values) are 'irrelevant', in particular regarding (free) stack space. The notion of 'irrelevant' is a bit vague, it means that the behaviour of the resulting program does not depend on those locations and also that it does not modify those locations. Moreover, we prefer an abstraction function rather than an relation between states to avoid admissibility issues for refinement. The central property is $t = \text{frame } A \ t_0 \ s$, for A being a set of addresses and t, t_0 and s being states. Think of A as the set of *allocated* addresses containing those pointers we want to *abstract* aka. eliminate.

thm *frame-def*

The standard use case we have in mind is $A \cap \text{stack-free } (h\text{td } s) = \{\}$, hence $A - \text{stack-free } (h\text{td } s) = A$, but nevertheless the intuition is:

- stack free typing from s is preserved, the framed sate has at least as many stack free addresses as the original one. So we can simulate any stack allocation.
- heap values for stack free and A are taken from reference state t_0 , this captures that we do not depend on the original values in s for those addresses.
- typing for allocations in A is taken from reference state t_0 , this captures that we do not depend on the original typing in s for those addresses.

By taking the same reference state t_0 to frame two states s and s' , we can express that the 'irrelevant' parts of the heap did not change in the respective framed states $\text{frame } A \ t_0 \ s$ and $\text{frame } A \ t_0 \ s'$.

rel-alloc, rel-stack, rel-sum-stack

The core invariant between the states that is maintained by the refinement is *rel-alloc* $\mathcal{S} \ M \ A \ t_0 \ s \ t$:

- \mathcal{S} is a static set of addresses containing the stack. Stack allocation and stack release are contained within \mathcal{S} .
- M is the set of addresses that might be modified by the original program.
- A is the set of addresses that are eliminated (abstracted) in the resulting program. Another good intuition about the set A is that the original function might read from and depend on those addresses but the resulting function does not. Moreover, the resulting function does not change any of heap locations in A . The resulting function is agnostic to those locations. It neither reads nor modifies them. For any heap valuation of A the abstract function simulates the original one.
- t_0 is the reference state explained above.
- s is the state of the original program
- t is the state of the resulting program.

thm *rel-alloc-def* [of $\mathcal{S} \ M \ A \ t_0$]

The properties of *rel-alloc* are:

- $t = \text{frame } A \ t_0 \ s$, the resulting heap in t is the same as the original in s , except for the addresses in A and the stack free space.
- $\text{stack-free}(\text{htd } s) \subseteq \mathcal{S}$: The stack free space is contained in \mathcal{S} .
- $\text{stack-free}(\text{htd } s) \cap A = \{\}$: We only want to eliminate properly allocated pointers, which are not contained in the stack free space.
- $\text{stack-free}(\text{htd } s) \cap M = \{\}$: We only mention properly allocated pointers to be modified. Modifications within the stack free space are irrelevant, as they are abstracted by the framing anyways.

For an original function f and the abstract aka. lifted function g the refinement property has the following shape: $rel\text{-}alloc \ \mathcal{S} \ M \ A \ t_0 \ s \ t \implies refines \ f \ g \ s \ t \ (rel\text{-}stack \ \mathcal{S} \ M1 \ A \ s \ t_0 \ (rel\text{-}xval\text{-}stack \ L \ R))$

Note that the output relation of $refines$ relates both the resulting states and return values to each other. The return values of the error monad are related by $rel\text{-}sum\text{-}stack$, taking a relation L for error values (Inl) and the R for normal termination (Inr).

thm $rel\text{-}sum\text{-}stack\text{-}def$

thm $rel\text{-}stack\text{-}def$ [of $\mathcal{S} \ M1 \ A \ s \ t_0 \ rel\text{-}sum\text{-}stack \ L \ R$]

Consider the output states s' and t' and the output values v and w for the original and the abstracted function. Then we have:

- $rel\text{-}xval\text{-}stack \ L \ R \ (hmem \ s') \ v \ w$: The result values are related, (see below).
- $rel\text{-}alloc \ \mathcal{S} \ M1 \ A \ t_0 \ s' \ t'$: In particular $t' = frame \ A \ t_0 \ s'$. Note that we use the same A and the same reference state t_0 as for the initial states. So this means that the abstract program g does not change the heap values and typing in A and does not depend on the values.
- $equal\text{-}upto \ (M1 \cup \text{stack-free} \ (htd \ s')) \ (hmem \ s') \ (hmem \ s)$: The original program only modifies pointers contained in $M1$ or in the stack free portions of the heap (e.g. by nested function calls).
- $equal\text{-}upto \ M1 \ (htd \ s') \ (htd \ s)$: Changes to the heap typing of the original program are confined within set $M1$.
- $equal\text{-}on \ \mathcal{S} \ (htd \ s') \ (htd \ s)$: The stack typing of the original program remains unchanged. Note that it might change temporarily by nested function calls but the stacking discipline restores the state. By construction we have $M1 \subseteq M$.

Stacking pointers: $rel\text{-}singleton\text{-}stack$, $rel\text{-}push$ The relation on the output value captures the idea that portions of the heap are stacked / tupled into result values. On the boundaries of a function the relation on error values L is always the trivial $\lambda\text{-}$. ($=$). Errors are terminal as there is no exception handling in C. Within the boundaries of a function there can be more complex relations reflecting the nesting of `break` / `continue` / `return` and `goto`. For ordinary values the values of pointers are tupled by $rel\text{-}singleton\text{-}stack$, in case the original function returned no result (void), or nested by $rel\text{-}push$ in case the original function returned some result.

thm $rel\text{-}singleton\text{-}stack\text{-}def$

thm $rel\text{-}push\text{-}def$

A typical relation is $R = \text{rel-singleton-stack } p$ for some pointer p . This means that the abstract value can be obtained by looking into the heap at pointer p : $\text{rel-singleton-stack } p \ h \ () \ v$ means that $v = h\text{-val } h \ p$. The heap of the original program is propagated down the into the relations. Similar $\text{rel-push } p \ (\lambda\cdot. (=)) \ h \ x \ (v, x)$ relates the result value x to the tuple (v, x) where $v = h\text{-val } h \ p$. Note that rel-push can be nested represent multiple output parameters. Depending on the role of the pointers there are additional assumptions about the pointers, in particular things like $\text{ptr-span } p \subseteq A$ or $\text{ptr-span } p \subseteq M$ and disjointness properties like $\text{distinct-sets } [\text{ptr-span } p, \text{ptr-span } q]$.

IOcorres

There is an additional predicate *IOcorres* which represents the result of the refinement proof in the canonical autocorres ideom that is used within the other phases. This form is what is expected when constructing the final theorem combining all autocorres layers $\llbracket L1corres \ ?check\text{-termination} \ ?Gamma \ ?c\text{-L1.0} \ ?c; L2corres \ ?st\text{-L2.0} \ ?rx\text{-L2.0} \ ?ex\text{-L2.0} \ ?P\text{-L2.0} \ ?c\text{-L2.0} \ ?c\text{-L1.0}; IOcorres \ ?P\text{-IO} \ ?Q\text{-IO} \ ?st\text{-IO} \ ?rx\text{-IO} \ ?ex\text{-IO} \ ?c\text{-IO} \ ?c\text{-L2.0}; L2Tcorres \ ?st\text{-HL} \ ?c\text{-HL} \ ?c\text{-IO}; corresTA \ ?P\text{-WA} \ ?rx\text{-WA} \ ?ex\text{-WA} \ ?c\text{-WA} \ ?c\text{-HL}; \bigwedge s. \text{refines } ?c\text{-WA} \ ?A \ s \ s \ (\text{rel-prod } \text{rel-liftE} \ (=)) \rrbracket \implies ac\text{-corres}' \ (\lambda\cdot. \text{Exception default}) \ (?st\text{-HL} \circ \ ?st\text{-IO} \circ \ ?st\text{-L2.0}) \ ?check\text{-termination} \ \{ \text{AssumeError}, \ \text{StackOverflow} \} \ ?Gamma \ (\lambda s. \ (?rx\text{-WA} \circ \ (\lambda v. \ ?rx\text{-IO} \ v \ (?st\text{-L2.0} \ s)) \circ \ ?rx\text{-L2.0}) \ s) \ (\lambda s. \ (?ex\text{-WA} \circ \ (\lambda e. \ ?ex\text{-IO} \ e \ (?st\text{-L2.0} \ s)) \circ \ ?ex\text{-L2.0}) \ s) \ (?P\text{-L2.0} \ \text{and} \ ?P\text{-IO} \circ \ ?st\text{-L2.0} \ \text{and} \ ?P\text{-WA} \circ \ ?st\text{-HL} \circ \ ?st\text{-IO} \circ \ ?st\text{-L2.0}) \ ?A \ ?c$

$\llbracket L1corres \ ?check\text{-termination} \ ?Gamma \ ?c\text{-L1.0} \ ?c; L2corres \ ?st\text{-L2.0} \ ?rx\text{-L2.0} \ ?ex\text{-L2.0} \ ?P\text{-L2.0} \ ?c\text{-L2.0} \ ?c\text{-L1.0}; IOcorres \ ?P\text{-IO} \ ?Q\text{-IO} \ ?st\text{-IO} \ ?rx\text{-IO} \ ?ex\text{-IO} \ ?c\text{-IO} \ ?c\text{-L2.0}; L2Tcorres \ ?st\text{-HL} \ ?c\text{-HL} \ ?c\text{-IO}; corresTA \ ?P\text{-WA} \ ?rx\text{-WA} \ ?ex\text{-WA} \ ?c\text{-WA} \ ?c\text{-HL}; \bigwedge s. \text{refines } ?c\text{-WA} \ ?A \ s \ s \ (\text{rel-prod} \ (=) \ (=)) \rrbracket \implies ac\text{-corres}' \ \text{Exn} \ (?st\text{-HL} \circ \ ?st\text{-IO} \circ \ ?st\text{-L2.0}) \ ?check\text{-termination} \ \{ \text{AssumeError}, \ \text{StackOverflow} \} \ ?Gamma \ (\lambda s. \ (?rx\text{-WA} \circ \ (\lambda v. \ ?rx\text{-IO} \ v \ (?st\text{-L2.0} \ s)) \circ \ ?rx\text{-L2.0}) \ s) \ (\lambda s. \ (?ex\text{-WA} \circ \ (\lambda e. \ ?ex\text{-IO} \ e \ (?st\text{-L2.0} \ s)) \circ \ ?ex\text{-L2.0}) \ s) \ (?P\text{-L2.0} \ \text{and} \ ?P\text{-IO} \circ \ ?st\text{-L2.0} \ \text{and} \ ?P\text{-WA} \circ \ ?st\text{-HL} \circ \ ?st\text{-IO} \circ \ ?st\text{-L2.0}) \ ?A \ ?c$. The *refines* version and the *IOcorres* version can be converted into each other by $\llbracket L1corres \ ?check\text{-termination} \ ?Gamma \ ?c\text{-L1.0} \ ?c; L2corres \ ?st\text{-L2.0} \ ?rx\text{-L2.0} \ ?ex\text{-L2.0} \ ?P\text{-L2.0} \ ?c\text{-L2.0} \ ?c\text{-L1.0}; IOcorres \ ?P\text{-IO} \ ?Q\text{-IO} \ ?st\text{-IO} \ ?rx\text{-IO} \ ?ex\text{-IO} \ ?c\text{-IO} \ ?c\text{-L2.0}; L2Tcorres \ ?st\text{-HL} \ ?c\text{-HL} \ ?c\text{-IO}; corresTA \ ?P\text{-WA} \ ?rx\text{-WA} \ ?ex\text{-WA} \ ?c\text{-WA} \ ?c\text{-HL}; \bigwedge s. \text{refines } ?c\text{-WA} \ ?A \ s \ s \ (\text{rel-prod } \text{rel-liftE} \ (=)) \rrbracket \implies ac\text{-corres}' \ (\lambda\cdot. \text{Exception default}) \ (?st\text{-HL} \circ \ ?st\text{-IO} \circ \ ?st\text{-L2.0}) \ ?check\text{-termination} \ \{ \text{AssumeError}, \ \text{StackOverflow} \} \ ?Gamma \ (\lambda s. \ (?rx\text{-WA} \circ \ (\lambda v. \ ?rx\text{-IO} \ v \ (?st\text{-L2.0} \ s)) \circ \ ?rx\text{-L2.0}) \ s) \ (\lambda s. \ (?ex\text{-WA} \circ \ (\lambda e. \ ?ex\text{-IO} \ e \ (?st\text{-L2.0} \ s)) \circ \ ?ex\text{-L2.0}) \ s) \ (?P\text{-L2.0} \ \text{and} \ ?P\text{-IO} \circ \ ?st\text{-L2.0} \ \text{and} \ ?P\text{-WA} \circ \ ?st\text{-HL} \circ \ ?st\text{-IO} \circ \ ?st\text{-L2.0}) \ ?A \ ?c$

26.18.3 Options

To control the in/out- parameter abstraction there are two options of `autocorres`:

- *skip-io-abs* a boolean which is *true* by default. This skips the complete phase for all functions.
- *in-out-parameters* which takes a list of in-out specifications for functions. As soon as there is at least one specification present the phase is enabled (taking precedence over *skip-io-abs*).

So to properly enable the IO phase you have two main choices to specify what should be done either in **init-autocorres** or subsequent calls to **autocorres**. You can only disable option *skip-io-abs* in **init-autocorres** and then provide the individual options for *in-out-parameters* in subsequent **autocorres** invocations, or you can already define all *in-out-parameters* already in **init-autocorres**.

More details on the options are provided in the following examples.

]in-out-parameters.c

In option *in-out-parameters* you provide a parameter specification for the functions you want to abstract. The parameter specs following the parameter name are

- *in*: pointer is only used as input to the function. The referenced value does not change during the function call.
- *out*: the pointer is only used to output a result from the function. The referenced value at the beginning is irrelevant, the abstracted function should return the referenced value at the end of the original function.
- *in-out* the pointer is used to input a value and to return a result.

When no specification is given for a function, the list is considered empty. This means that the signature of the function shall not be changed by the abstraction. Pointer parameters in the original function stay pointer parameters in the resulting function. Note that this has a quite different effect from just skipping the phase, as autocorres is still attempting to do a proper refinement proof. More details are provided by the examples.

```

```

inc'

```

The function `inc` increments the value which is passed as a pointer `y`.

```

void inc (unsigned* y) {
    *y = *y + 1;
}

```

When we abstract this function to have an in-out parameter instead, we obtain a function like:

```

void inc (unsigned y) {
    y = y + 1;
    return y;
}

```

Note that this is now a pure function, that does no longer depend on the heap. This is also the final output of `autocorres` in `inc' ?y ≡ ?y + 1`:

```

thm inc'-def

```

Let us zoom into the refinement step from L2 to IO.

```

thm l2-inc'-def
thm io-inc'-def

```

Note that the type of parameter `y` changes from a pointer type to a value type. Here is the generated refinement theorem.

```

thm io-inc'-corres
lemma c-guard y ⇒
    distinct-sets [ptr-span y] ⇒
    ptr-span y ⊆ A ⇒
    ptr-span y ⊆ M ⇒
    globals.rel-alloc S M A t0 s t ⇒
    refines
    (l2-inc' y)
    (io-inc' (h-val (hrs-mem (t-hrs-' s)) y)) s t
    (globals.rel-stack S (ptr-span y) A s t0 (rel-xval-stack (rel-exit (λ- - . False)))
    (rel-singleton-stack y)))

```

by (rule *io-inc'-corres*)

Parameter y was specified as *in-out*. So function *io-inc'* becomes the actual value of the pointer passed in: $h\text{-val } (hrs\text{-mem } (t\text{-hrs-}' s)) y$. To discharge the *c-guard* y guards within the body of *l2-inc'* we need the assumption that the guard holds at the beginning. As we attempt to abstract pointer y we have its pointer span included in set A . Moreover, the content of pointer y is modified by *l2-inc'* hence it appears in M as well as explicit in the final relation *globals.rel-stack*. Pointer parameters are assumed to be distinct. As we have only one parameter the assumption trivially *distinct-sets* [*ptr-span* y] holds. Note that set A is only constrained by *ptr-span* $y \subseteq A$. So we could instantiate it with the universal set *UNIV*. Recalling the meaning of A this means that the resulting function *io-inc'* is a pure function, in the sense that it does not depend on the heap anymore. The relation for the termination with **exit** is *rel-exit* ($\lambda\text{-} - \text{-} . False$), which expresses that this path is unreachable for the current function. The function will never terminate with **exit**.

call-inc-parameter'

Next we look at a function that calls our previously defined integer function on a pointer to its parameter.

```
unsigned call_inc_parameter(unsigned n) {
    inc(&n);
    return(n);
}
```

After autocorres the function is just a mere wrapper to the increment function

thm *call-inc-parameter'-def*

Here are the relevant definitions and the IO refinement theorem.

thm *l2-call-inc-parameter'-def*

thm *io-call-inc-parameter'-def*

thm *io-call-inc-parameter'-corres* [*no-vars*]

thm *io-call-inc-parameter'-corres*

lemma *distinct-sets* ($[\]::\text{addr set list}$) \implies

globals.rel-alloc $\mathcal{S} M A t_0 s t \implies$

refines

(*l2-call-inc-parameter' n*)

(*io-call-inc-parameter' n*) $s t$

(*globals.rel-stack* $\mathcal{S} \{ \} A s t_0$ (*rel-xval-stack* (*rel-exit* ($\lambda\text{-} - \text{-} . False$)) ($\lambda\text{-} . (=)$)))

by (rule *io-call-inc-parameter'-corres*)

Note that here we do not have any assumption on the set A and the modified variables in the final state are empty. This is because we eliminate

a pointer to a temporary stack variable that is out of scope after the function and in the beginning of the function it is part of the *stack-free* space.

const*keep-inc'*

Now let us consider a copy of the increment function were we do not convert to in out parameters but leave it as it is. Unsurprisingly, the resulting function still operates on pointers.

thm *keep-inc'-def*

Let us look into the IO corres phase.

thm *l2-keep-inc'-def*

thm *io-keep-inc'-def*

thm *io-keep-inc'-corres*

lemma *distinct-sets* [*ptr-span y*] \implies

ptr-span y \cap *A* = {} \implies

ptr-span y \cap *stack-free* (*hrs-htd* (*t-hrs-' s*)) = {} \implies — FIXME: redundant assumption?, follows from the next ones

globals.rel-alloc *S M A t₀ s t* \implies

ptr-span y \subseteq *M* \implies

refines

(*l2-keep-inc' y*)

(*io-keep-inc' y*) *s t*

(*globals.rel-stack* *S* (*ptr-span y*) *A s t₀* (*rel-xval-stack* (*rel-exit* (λ - - -. *False*)))

(λ -. (=)))

by (*rule io-keep-inc'-corres*)

As pointer *y* is an allocated pointer that we do not abstract it should not belong to *A* and must not collide with *stack-free* space. As we might modify the pointer it is contained in *M* as well as the final modifies set.

Note that the bodies of *io-keep-inc'* and *l2-keep-inc'* are equivalent but the refinement statement is not a trivial statement and in particular is not the same as when skipping the IO corres phase. For example from the refinement statement we can derive that any heap location different from *ptr-span y* is unchanged.

Next let's look what happens when we call this function on a local parameter.

keep-call-inc-parameter'

thm *keep-call-inc-parameter'-def*

thm *io-keep-call-inc-parameter'-def*

thm *l2-keep-call-inc-parameter'-def*

thm *io-keep-call-inc-parameter'-corres* [*no-vars*]

lemma *distinct-sets* ([*addr set list*]) \implies

```

globals.rel-alloc  $\mathcal{S} M A t_0 s t \implies$ 
refines
  (l2-keep-call-inc-parameter'  $n$ )
  (io-keep-call-inc-parameter'  $n$ )  $s t$ 
  (globals.rel-stack  $\mathcal{S} \{\}$   $A s t_0$  (rel-xval-stack (rel-exit ( $\lambda - - . False$ )) ( $\lambda - . (=)$ )))
by (rule io-keep-call-inc-parameter'-corres)

```

The local variable pointer is still present in the final function. Still the refinement statement indicates that we have a ‘pure’ functions, as we do not have constraints on A and also do not modify anything. The notion of pure we use here, is that the function does not depend on proper heap pointers. The *stack-free* space that we temporarily use is excluded by our definitions of *globals.frame*, *globals.rel-alloc* and *globals.rel-stack*.

safe-add'

This function is an example of an arithmetic function that checks for overflows. The status of the check is the return value and the result of the operation is passed via pointer. We make an in-out parameter for the result. So the final function returns a tuple of the result value and the status (*rel-push* in the refinement statement).

26.18.5 Handling exit in function calls

When we call a function that was refined by in-out-parameters there are various cases we have to consider, e.g. do we pass in a heap pointer or a local pointer, do we eliminate the local pointer or keep it? In general when we pass in a pointer that is not supposed to be eliminated as an in-out parameter we first pass in the dereferenced value and after the function returns we take the value from the embellished result and assign it to the pointer. So the pointer assignment that would take place in the middle of the called function in the original program, is moved outside of the call in the refined program. After this the heaps of the original program and the refined program are in sync again at the pointer. To establish the heap refinement it turns out that we also have to bring the heaps in sync again even if the function terminates with `exit`. We catch the `exit`, update the heap and

then re-throw the *exit*. So the called function also returns embellished exit values which hold the value of the relevant pointers. This extra work is a little annoying as the `exit` terminates the complete program and usually we do not catch an `exit`. So this step might introduce *L2-catch* to wrap up the procedure call. Note that this is currently the only remaining use case for *L2-catch*, the other occurrences of *L2-catch* were already transformed to *L2-try* as post processing in phase L2 when we move from ‘flat’ exception handling to ‘nested’ exception handling.

thm *call-inc-int-ptr'-def*

26.18.6 Global Heap Pointers

A core part of the IO phase is to keep track of pointers and in particular to do some bookkeeping of the parts of the heap that might get modified. This analysis and bookkeeping is focused around the pointers that are visible in the signature of a function. This fails short as soon as pointers to global heap are used within the body of a function, which are not mentioned in the function signature. To handle some common use cases with global heap we have a mechanism to over-approximate the impact of a function on the heap by referring to a static set \mathcal{G} of addresses that should not be abstracted by the IO phase. We can annotate a function to make use of this mechanism by mentioning them in **init-autocorres** with the option `in_out_globals`. For the refinement statement we assume that

- $\mathcal{G} \cap A = \{\}$: pointers in \mathcal{G} are not supposed to be abstracted, and
- $\mathcal{G} \subseteq M$: the function might modify any global variable.

Within the body of such a function (marked with option `in_out_globals`), whenever a pointer is used which does not occur in the signature as pointer parameter and is specified otherwise we assume that this pointer a global pointer and assert this formally by adding a guard *ptr-span* $x \subseteq \mathcal{G}$. If a function has multiple pointer parameters we also assert disjointness of pointers.

26.18.7 Disclaimer / Caution

As we have seen in the examples the refinement theorems can contain assumptions on the input pointers, in particular disjointness assumptions between different pointer parameters and also disjointness of pointer parameters to complete memory areas like *stack-free*. When a function is called these assumptions have to be discharged. When these pointer parameters are eliminated (replaced by in-out value parameters) the assumptions disappear. So when you work on the final output of `autocorres` you know nothing about pointers or disjointness.

In case a local pointer is eliminated these assumptions are be discharged locally as an intermediate step in the proof. So this use case is fine. However, if the function is called on a heap pointer these assumptions are propagated to the caller. So the assumptions move up the call stack and might end up as implicit hidden assumptions on your toplevel functions (API).

Rule of thumb: In case your toplevel API function has more then one pointer parameter don't specify any in-out parameters on that function to avoid implicit assumptions.

26.18.8 Implementation Aspects

The proof of the refinement theorem requires to keep track of various pointers and changes the signature of functions, including extending plain return values to tuples. We decided to make a rather explicit forward proof for this, to keep tight control of the various aspects. We make heavy use of ML antiquotations to match and build cterms. An obstacle here is that the state record *globals*, which holds the heap, is not yet defined but is only present as a locale. So our code is implemented within the locale

stack-heap-state. We have introduced the concept of *interpretation data* (c.f. `../lib/ml-helpers/interpretation_data.ML`) to get hold of the interpretation we are interested in. The data is initialised in `../AutoCorres.thy` as declaration within *stack-heap-state*. In particular this allows us to match against and build heap lookup and heap update expressions.

The interface is via `In_Out_Parameters.operations`. This takes the morphism of the interpretation as an argument to derive the instance we are interested in. Note that we have crafted the main functions to benefit from the eager evaluation of ML. In particular `In_Out_Parameters.operations` takes the morphism *phi* as its only parameter and thus the instances of the main functions are only evaluated once.

end

26.18.9 pointer-parameters as data

In a case where a pointer is not used to access the heap (e.g., *set-void*), the "modifies" part of the corres theorem should be empty. Otherwise functions like *set-byte*, that pass "arbitrarily" computed pointers fail to get IO-lifted. We enforce this by declaring pointer parameters as "data" in the *in-out-parameters* option of autocorres.

Future work: Automate this analysis to infer which pointer-parameters are treated as pure data.

context *io-corres-set-void* **begin**

end

26.18.10 Future work / Open Ends

- Support function pointers
- support functions that might modify the heap typing (e.g. via *exec-concrete*) currently our *rel-alloc* / *rel-stack* setup enforces that heap typing does not change at all this is too restrictive. Before we had that heap typing

does not change in \mathcal{S} which was too weak to modify the A frame to handle invocations on heap pointers. I guess a good approximation would be to say that heap typing is unchanged on all relevant addresses: $\mathcal{S} \cup A \cup M$ Including M might be too restrictive, e.g. consider an alloc function that zeros some memory and adapts the heap-typing.

- Refined treatment of *in-out-globals*: allow the user to add a guard that is inserted in front of the abstract program. E.G. locale for procedure: $ptr\text{-}span\ (global\text{-}array + MAX\text{-}IDX) \subseteq \mathcal{G}$ + a Guard depending on a parameter idx , e.g. $idx < MAX\text{-}IDX$. Then we can automatically discharge local guards like $ptr\text{-}span\ (global\text{-}array + idx) \subseteq \mathcal{G}$. Not sure if this is useful though
- Cleanup unused *Generic-Data* that was replaced by interpretation data
- Remove struct-rewrite step from Heap Lifting. As we normalise pointers to root pointers in L2-Opt the pointers should already be in normal form and struct-rewrite does nothing.
- Add sanity checks to *in-out* specs, especially if parameter names actually occur in signature
- Remove redundant assumptions for keep parameters: $ptr\text{-}span\ y \cap stack\text{-}free\ (hrs\text{-}htd\ (t\text{-}hrs\text{-}'\ s)) = \{\} \implies globals.\text{rel}\text{-}alloc\ \mathcal{S}\ M\ A\ t_0\ s\ t \implies ptr\text{-}span\ y \subseteq M \implies \dots$
 - The first one can be derived from the following ones
- Peephole: remove *ptr-disjoint* of singletons
- Peephole simplification, especially Guard True. Not really necessary, will disappear in hl anyways.
- Eliminate pointers to global variables: When a pointer to a global variable is only used as a *in-out parameter* it would be nice to abstract it to a record field in *lifted-globals* (or to something similar, i.e. lookup / update function in the heap with disjointness and commutation of updates for other globals)
- Support more relaxed disjoint assumptions, especially *disjoint-or-eq*, e.g. swap also works if the input pointers are equal.
 - All ‘keep’ pointers are currently assumed disjoint and also are in the modifies set. We could be more relaxed here.
- HL phase has some explicit references to phase L2 instead of abstract *prev-phase* (probably related to function pointers)

- Would be nice if synthesize rules would also participate in thm, and add / del stuff like *named-rules*

end

26.19 Function Pointers

```
theory fnptr
imports AutoCorres
begin
```

```
install-C-file fnptr.c
```

```
autocorres [
  ts-force nondet = voidcaller,
  ts-force-known-functions = option ] fnptr.c
```

Dealing with function pointers in AutoCorres has the following main challenges:

- Parameter passing
- Correspondence proofs
- Mutual recursion

Parameter passing

In C a function pointer type does not have to specify the names of the function parameters. Hence when translating a call to a function pointer from C into SIMPL we need a uniform way to pass the function parameters. Recall that in SIMPL local variables are represented as part of the state, there is no lambda binding at that stage. For ordinary function calls we know the names of the parameters and can refer to them, for function pointers we do not know the names. Our approach is to generally switch to uniform names for the parameters, encoding the position and the type like: *in1-int*, *in2-unsigned*.

The mapping to the original names in the C file is implemented as syntactic sugar in the locale. As this mapping depends on the actual function we have to make sure to work in the correct context. The main interface to this mapping is defined in `../c-parser/HPInter.ML` e.g.:

- `HPInter.all_locvars`

- `HPInter.enter_scope`

Note that the current implementation is a little bit fragile as it also depends on the syntax translations for lookup and update in the underlying `statespace`.

Correspondence proofs

When we come along a function pointer call in a correspondence proof we need a correspondence proof for the function pointer. Where to we get it from? In full generality we do not know much about where the function pointer might be pointing to. One drastic way out could be to add a guard at the call point, which guarantees that there is such a proof. This makes the proof trivial, but the code gets polluted with correspondence guards which also show up at the user level. So whenever one wants to prove a property about the resulting function one has to deal with this guard.

To keep the user level proofs clean, we decided to take another approach, by restricting the programs we can handle to some common use cases:

- Constant function pointer as parameter to a function. Here constant means that the parameter is not modified within the function body.
- Function pointer via constant global variable. Think of the global variable as a kind of dispatcher or class table, e.g. Array of structs representing "object descriptions" with function pointers as fields.
- C-style object method calls: Instead of a pure function pointer, a pointer to a structure which contains function pointers is passed as a parameter.

In the first case we can add the correspondence assumption to the locale of the function. In the second case we can even resolve the correspondence proof as we can statically infer which functions might be called via the global variable.

Mutual recursion

The general approach to resolve a function pointer call is via a lookup in a program environment which maps the pointer to the definition of the function. In SIMPL the function is defined by a piece of syntax, and the program environment is an explicit context Γ which appears in the semantic rules for SIMPL. Moreover, for each function that might be called via a function pointer we introduce a pointer to that function. These pointers, and the assumption that all of them are distinct are put to the locale of global variables.

In each phase of Autocorres we introduce a similar program environment \mathcal{P} that maps the pointer to a monadic HOL function definition. As from phase L2 on the parameters of functions become lambda abstractions we introduce a distinct program environment for each function type. These program environments are introduced as locale parameters. Then we successively add the implementation equations of the form \mathcal{P} *some-function-pointer* = *some-function* as the functions are defined.

The correspondence theorems (or assumptions) for function pointer calls then relates the functions resolved via their respective environment, e.g. relate *the* (Γ p) with \mathcal{P} p .

We also support mutual recursion via global function pointers (case 2 above), e.g. a function might call itself indirectly via a global function pointer variable. The global program analysis takes this into account to determine the strongly connected components aka. (recursive) cliques.

This adds another twist to the approach with program environments just described. The assumption \mathcal{P} *some-function-pointer* = *some-recursive-function-via-P* can only be added after the function *some-recursive-function-via-P* is defined, but the definition already depends on the program environment. How do we cut the loop?

The core idea is to split the definition into two phases. First we define the **fixed-point** by explicitly extending the program environment at each call. Instead of calling \mathcal{P} p directly we call *map-of-default* \mathcal{P} [(*some-function-pointer*, *some-recursive-function-via-P*)] p where *some-recursive-function-via-P* participates in the fixed point construction. Once the function is defined, we create a new locale, extending the program environment with the assumption \mathcal{P} *some-function-pointer* = *some-recursive-function-via-P* and simplifying

$$\text{map-of-default } \mathcal{P} \text{ [(some-function-pointer, some-recursive-function-via-P)]}$$

$$p = \mathcal{P} p$$

in the function body. After this extra step we again uniformly represent recursive and non-recursive function pointer calls with \mathcal{P} p .

26.19.1 Global locales

The global locales fix the program environments (mapping function pointers to definitions) for a phase. These locales are created in the initialisation phase of **autocorres** before the individual functions are processed.

The fundamental locale is storing the addresses of global variables, including function pointers and some basic properties about them.

context *fnptr-global-addresses*
begin

For each function pointer a constant is declared e.g. *fnptr.odd-disp*, *fnptr.add*. Note that these constants have to be qualified by the program name. In case there would be a conflict with Isabelle internal names, e.g.

a function ending with `--` the name is suffixed with `Hoare.proc_deco`, cf. `NameGeneration.fun_ptr_name`.

ML \langle *Hoare.proc-deco* \rangle

Moreover the global variables and their defining equations, i.e. initialisation expressions are collected in $odd\text{-}even\text{-}dispatcher \equiv fupdate\ (Suc\ 0)\ (\lambda\cdot\ fnptr.\ even\text{-}disp)\ (fupdate\ 0\ (\lambda\cdot\ fnptr.\ odd\text{-}disp)\ (ARRAY\ \cdot\ NULL))$

$gi \equiv 0$

$dispatcher\text{-}u \equiv fupdate\ (Suc\ 0)\ (unop\text{-}u\text{-}C\text{-}update\ (\lambda\cdot\ fnptr.\ inc\text{-}u))\ (fupdate\ (Suc\ 0)\ (binop\text{-}u\text{-}C\text{-}update\ (\lambda\cdot\ fnptr.\ add\text{-}gu))\ (fupdate\ 0\ (unop\text{-}u\text{-}C\text{-}update\ (\lambda\cdot\ fnptr.\ inc\text{-}u))\ (fupdate\ 0\ (binop\text{-}u\text{-}C\text{-}update\ (\lambda\cdot\ fnptr.\ add\text{-}u))\ (ARRAY\ \cdot\ object\text{-}u\text{-}C\ NULL\ NULL))))$

$dispatcher \equiv fupdate\ 4\ (object\text{-}C.\ unop\text{-}C\text{-}update\ (\lambda\cdot\ NULL))\ (fupdate\ 4\ (binop\text{-}C\text{-}update\ (\lambda\cdot\ NULL))\ (fupdate\ 3\ (object\text{-}C.\ unop\text{-}C\text{-}update\ (\lambda\cdot\ fnptr.\ inc))\ (fupdate\ 3\ (binop\text{-}C\text{-}update\ (\lambda\cdot\ fnptr.\ minus))\ (fupdate\ 2\ (object\text{-}C.\ unop\text{-}C\text{-}update\ (\lambda\cdot\ fnptr.\ dec))\ (fupdate\ 2\ (binop\text{-}C\text{-}update\ (\lambda\cdot\ fnptr.\ mul))\ (fupdate\ (Suc\ 0)\ (object\text{-}C.\ unop\text{-}C\text{-}update\ (\lambda\cdot\ fnptr.\ dec))\ (fupdate\ (Suc\ 0)\ (binop\text{-}C\text{-}update\ (\lambda\cdot\ fnptr.\ minus))\ (fupdate\ 0\ (object\text{-}C.\ unop\text{-}C\text{-}update\ (\lambda\cdot\ fnptr.\ inc))\ (fupdate\ 0\ (binop\text{-}C\text{-}update\ (\lambda\cdot\ fnptr.\ add))\ (ARRAY\ \cdot\ object\text{-}C\ NULL\ NULL))))))))))$

$add\text{-}u\text{-}p \equiv fnptr.\ add\text{-}u$

$add\text{-}p \equiv fnptr.\ add$.

thm *global-const-defs*

thm *global-const-array-selectors* — more efficient access to array components

thm *global-const-non-array-selectors*

thm *global-const-selectors*

To express distinctness of function pointers we make use of the infrastructure in `$ISABELLE_HOME/src/HOL/Statespace/DistinctTreeProver.thy`, which is also the foundation for `statespace`. A tree data structure is used to efficiently derive distinctness and subset properties.

thm *fun-ptr-distinct*

thm *fun-ptr-subtree*

For every function pointer the locale assumes that they are not NULL, i.e. *c-fnptr-guard*. Based on the distinctness of the function pointers we derive some simplification rules for *map-of-default*.

thm *fun-ptr-simps*

end

Note that the program environment \mathcal{P} for l1 programs is only declared as constant (without a definition). This environment is 'populated' in derived locales as the definitions of function become available.

A program environment for each distinct function pointer type is introduced for each further phase. e.g. $\mathcal{P}\text{-}l2\text{-}unsigned\text{---}unsigned$, $\mathcal{P}\text{-}l2\text{-}int\text{---}int$

context *fnptr-global-addresses*

begin

For example if the function pointer would index into the dispatcher array *dispatcher-u* and select a *binop-u-C*, it would result into subgoals for each of the possible pointers, namely and *fnptr.add-u* *fnptr.add-gu*.

term *dispatcher-u*

In this bundle we define some introduction rules to support the correspondence proofs. In phase L1 and L2 the correspondence proof is quite explicitly done in ML and the rules for function pointer calls are explicitly instantiated in ML. Here in layer HL the proof is done by applying intro rules and synthesising the abstract version of the program. The following rules relate the abstract and concrete program environments that are used for function pointer calls.

context includes *fnptr-hl-impl-corres*

begin

thm *fun-ptr-intros*

end

Note for example, that in the current goal state the concrete program would be of the shape $\mathcal{P}\text{-}l2\text{---}int\ p$ whereas the abstract program would be a plain schematic variable. This variable is then instantiated with $\mathcal{P}\text{-}hl\text{---}int\ p$. Once the rule is applied the identity marker *DYN-CALL* triggers the sidecondition splitter / solver: `AutoCorresUtil.dyn_call_split_simp_sidecondition_tac`, which splits the generic correspondence of some generic function pointer to its possible values.

For example if the function pointer would index into the dispatcher array *dispatcher-u* and select a *binop-u-C*, it would result into subgoals for each of the possible pointers, namely *fnptr.add-u* and *fnptr.add-gu*.

context includes *fnptr-wa-impl-corres*

begin

Like in phase HL we also have some custom intro rules to support the instantiation of function pointer calls.

thm *fun-ptr-intros*

thm *global-const-defs*

thm *fun-ptr-simps*

end

The TS phase adds another dimension to the program environments, the monad type. E.g. $\mathcal{P}\text{-}pure\text{-unsigned}\text{---}unsigned$, $\mathcal{P}\text{-}gets\text{-unsigned}\text{---}unsigned$, $\mathcal{P}\text{-}option\text{-unsigned}\text{---}unsigned$, $\mathcal{P}\text{-}nondet\text{-unsigned}\text{---}unsigned$, $\mathcal{P}\text{-}exit\text{-unsigned}\text{---}unsigned$.

context includes *fnptr-ts-impl-corres*

begin

Again we have custom intro rules to support instantiation of the abstract program environment.

```

```

This function performs a function pointer call on a function parameter. Recall that we only support the case where the function pointer parameter value stays the same within the function. The phase L1 is special, as we postpone the correspondence proof of the function pointer call to the L2 layer. The reason is that in the L2 layer we replace the parameters with lambda abstraction and thus the fact that the value does not change becomes trivial. In L1 we would have to propagate this information through every state update, from the invocation of the function to the function pointer call. This proof is anyway performed in the L2 phase. Postponing the correspondence proof is achieved by just assuming the correspondence in *L1-guarded*.

thm l2-def
end

```

```

context l2-corres-parameter-call
begin

```

In contrast to the function pointer call via a global variable, where we statically resolve which functions are potentially called, we add an explicit assumption on the parameter to the correspondence theorem. As in phase L2 we also have to proof the postponed L1 correspondence we actually have both assumptions here.

```

thm l2-parameter-call'-corres
thm l2-corres
thm l2-def
end

```

When defining (mutual) recursion indirectly via function pointers, there is a subtlety in the definition of the functions. In order to have an admissible *L2corres* property the program environment for the current clique is temporarily explicitly extended via *map-of-default* in the function bodies. After definition of the function and extending the hypothetical program environment with the new definitions this construction is hidden again.

Compare the variation of `in` in *l2-corres-odd-disp-even-disp* vs. *l2-impl-odd-disp-even-disp* and the extended program environment in *gets-the* (*ogets* $(\lambda-. ?f)$) = *return* *?f*

gets-the (*ogets* *?f*) = *gets* *?f*.

Also recall the general flow of how to arrive at a new level with definition and correspondence proof.

- First the induction step of the correspondence proof is performed, assuming that the recursive calls are in the correspondence relation.
- If that proof is successful the function body or bodies are used to do the actual definition(s) of the function(s).

- After the definition is done the actual correspondence proof is performed using the induction step as major ingredient, replacing the body / bodies with the new definition(s).
- The program environments are extended with the assumptions that the pointers are mapped to the new definitions and the right hand sides of the definitions are simplified.

Recall that in case of a function pointer call via a parameter we assume correspondence of the parameter. So in which monad should we end up? Which monad should we assume for the parameter? Currently we assume the same monad as for the function. We consecutively try the correspondence from the most restrictive to the most expressive monad and we end up in the monad with the first successful proof. If you want a different (more expressive) monad you can configure this via the autocorres option *ts-force*.

end

```

Method calls of C-style objects

The goal is to also support function pointer invocations via C-style object methods: Instead of a plain function pointer a function gets a pointer to a structure (object) that contains function pointers as structure fields. This adds an important twist to the refinement proofs of autocorres. When we invoke a method via `p->method(...)` we actually calculate the function pointer from the heap object referenced by pointer `p`. As with the cases described before at that point we have to argue that the referenced function fulfills the 'corres' predicate. However, now we have the indirection via the heap. So somehow we have to keep track of the function pointers stored in the heap. As other pointer objects might also be stored and manipulated in the heap this typically requires user-level reasoning about the heap layout and disjointness of certain pointers. As autocorres is mainly used as a preprocessing tool for arbitrary C programs we want to avoid making too restrictive assumptions here. Instead we postpone the argument to the user. The core idea is that we want to argue that the actually referenced function is a 'known function' for which we know or can assume that the 'corres' predicate holds. We introduce a predicate *known-function* into our locale hierarchy, which takes a function pointer *p* and tells us if this is a known function for which we can assume 'corres'. On every invocation of a object method we introduce a guard *known-function (method p)* into the code. Autocorres can then utilise this guard together with the assumption that the correspondence holds for all known functions. It is then left as an exercise for the user to discharge the guards. This boils down to an invariant argument that every time you assign something to *method p* it has to be a *known-function*. To support this, everytime a function is defined which might be such a function pointer, we utilise the implementation locales to store the information that this is a *known-function*.

Here are the locales about the *known-function* which state correspondence. These are imported as parents in all individual corres locales.

```

context fnptr-l1-corres

```

```
begin  
thm known-function-corres  
end
```

```
context fnptr-l2-corres  
begin  
thm known-function-corres  
end
```

```
context fnptr-hl-corres  
begin  
thm known-function-corres  
end
```

The locales for phases WA and TS are special as they might change the signature of the resulting function depending on the called functions. We make assumptions about called methods to derive the definition of the calling function. E.g. for phase WA we have to know whether a called method will do signed or unsigned word abstractions. For phase TS we have to know in which monad the called methods are defined in order to select the right monad for the caller. We can use the autocorres options `ts_force_known_functions`, `unsigned_word_abs_known_functions` and `no_signed_word_abs_known_functions` analogous to the corresponding options for individual functions.

In our example program we have chosen the option monad as a result monad. Note that autocorres does some sanity checks to ensure that e.g. the chosen monad is expressible enough, but ultimately it is the responsibility of the user to ensure that the monad and the word abstraction options match all potential instances of the methods.

```
context fnptr-wa-corres  
begin  
thm known-function-corres  
end
```

```
context fnptr-ts-corres  
begin  
thm known-function-corres  
end
```

```

26.20.1 Union support in C-Parser and Autocorres

Fully fledged C unions can have a lot of semantic subtleties in particular with respect to undefined behavior when it comes to different padding in the variants, effective types and accessing the union via different variants, e.g. writing a pointer through one variant and subsequently reading or writing the same union via another variant. See for example <https://robbertkrebbers.nl/research/thesis.pdf> in subsections 2.5.5 ff. for a discussion of some fine points.

Our current solution is very pragmatic by only supporting a subset of unions that does not exhibit the more "weired" behaviours:

- Single variant unions
- Multi-variant unions where each variant is packed (no implicit padding) and has the same size.

For these limited unions the semantics is deterministic and basically boils down to casting / coercing different C-types. Note that every *c-type* is equipped with conversions *from-bytes* and *to-bytes* which allows us to take a value, convert it to a byte list and then make another

value (potentially with a different type) from that byte list again. So the basic machinery is already there.

The C parser analyses which variants of a union are actually actively used in the code you want to verify. Only those variants (internally referred to as active variants) are taken into account. If there is only a single variant we are fine and a single record type is constructed in HOL as the C-type representing that type. It is the same construction as for a structure type of that variant.

In case there are multiple active variants the C parser checks that all those variants have the same size and are *packed* which means that there is no padding. The original C code might have to be rewritten with explicit padding fields to fulfill this requirement.

We create a record type for each variant of the union, like a 'struct' for each variant. One variant is considered as the *canonical* variant. Currently this always is the first variant of the union. The idea of the canonical variant is that every access or update to a union is always done via this canonical variant and then 'casted' to the variant you need. This casting is implemented via *PTR-COERCE*('a → 'b) for pointers and *COERCE*('a → 'b) and *coerce-map* for values.

Example:

```
typedef struct {
    unsigned fst;
    unsigned snd;
} unsigned_pair;
```

```
typedef struct {
    signed fst;
    signed snd;
} signed_pair;
```

```
typedef union {
    unsigned_pair u;
    signed_pair s;
} open_union;
```

The union *open-union* has two variants. The first one *u* is considered to be the canonical one. So when you want to update a variant *s* in the heap via a pointer to *open-union* we first read the canonical variant *u* from the heap then coerce the value to a variant *s*, then the update on the value is performed then the resulting value is coerced back to variant *u* and finally written back to the heap.

A good mental model for this implementation is that accesses to unions are normalised towards the canonical variants of the root pointers. This also carries over to the split heap model you obtain when you perform the HL phase of autocorres. There is only one relevant heap for the union, which is the heap for the canonical variant. This means that you can also define *addressable-fields* for the canonical variant. Currently you cannot define *addressable-fields* for the other variants.

```
include-C-file union.h for union.c
install-C-file union.c
autocorres [addressable-fields = open-union.u] union.c
```

```
context union-all-corres
begin
thm ts-def
thm l2-def
```

Names

The union *open-union* has two variants *u* and *s*. The first one, *u*, is considered to be the canonical one. The corresponding c-type becomes "THE" type of union and is named *open-union-C*. The other variant *s* gets the qualified name *open-union-C's-C*.

```
term open-union-C
term u-C
thm u-C-def
term u-C-update
thm u-C-update-def
```

```
term open-union-C's-C
term s-C
thm s-C-def
term s-C-update
thm s-C-update-def
```

```
term heap-open-union-C
thm heap-open-union-C-def
```

Anonymous Structures and Union

For anonymous structures and types we create names by considering the surrounding typedef and structure / union. For example see the typedef of *my-union*. The canonical variant for the union gets *my-union-C*. The variant *f* is an anonymous structure. The type of the anonymous structure is type *my-union-C'f-C'struct*, whereas the type of the variant *f* is *my-union-C'f-C*. Analogously there is also a suffix *union* in case of an anonymous union. Note the naming convention: For nested names note that suffix *union* or *struct* is for the nested union or structure itself, in contrast to the name without suffix which denotes the variant of the enclosing union.

```
typ my-union-C  
term my-union-C
```

```
typ my-union-C'f-C'struct  
term f1-C  
thm f1-C-def
```

```
typ my-union-C'f-C  
term f-C  
thm f-C-def
```

```
typ my-union-C'g-C'union  
term x1-C  
thm x1-C-def
```

```
typ my-union-C'g-C  
term g-C  
thm g-C-def
```

Lemmas to coerce values / heap accesses

```

26.21 Pointers into Structures in Split Heap

```
theory open-struct
  imports AutoCorres
begin
```

26.21.1 Overview

Heap lifting in AutoCorres transforms the monolithic byte-level heap *heap-mem* with explicit term level heap type description *heap-typ-desc* and typing constraints, like *c-guard*, *h-t-valid* and $d \models_t p$ to a more abstract split heap model with implicit HOL-typing. The major advantage of the split heap model is that, updates to one particular heap do not affect all other distinct heaps, removing the obligation to explicitly take care about aliasing. Aliasing between different heaps is ruled out by the model already.

The question that arises is on which granularity do we split the byte-level heap? The original AutoCorres splitted at the granularity of types. Each distinct c-type is mapped into a separate heap. In that model you can still have intra-type aliasing (i.e. pointers of the same type can alias), but no inter-type aliasing (i.e. pointers of different type are distinct, and cannot alias). As an example a pointer to a list structure refers to a different (split) heap as a pointer to a tree structure. So when a function modifies lists, no pointer to a tree is affected.

Of course not every C-program can be represented in this split-heap model. In those cases the abstraction fails. In particular think of a low-level memory allocator, that allocates some raw-bytes and delivers a void-pointer, that is then retyped to point to the actual structure. To be able to combine those byte-level functions with high-level typed functions (in the split heap) one can switch between both layers of abstraction by *exec-concrete* and *exec-abstract*. The good thing is that this gives us a very expressive tool to switch between byte-level and typed view. We can do the specification and proofs of different parts of the program on the adequate level and still combine the results. But switching between the layers can be tedious and thus should be limited to the low-level functions that really inherently need byte-level reasoning.

Unfortunately the type granularity of the split heaps also rules out programs dealing with pointers into a structure. For example a structure containing a *int* field *count* cannot pass a *int* pointer to that field *count* to a another function, that might update it. The complete structure has a separate (split) heap that is distinct from the heap containing *ints*. This would mean that we have to resort to the byte-level heap to reason about those functions.

We extended the split heap model to support this common use-case. The core idea is that in addition to split heaps on the granularity of types you can also specify split heaps on the granularity of structure fields. Conceptually you 'open' the structure into its components (aka. fields) and each field gets a separate heap. Additionally you can specify which fields should be *addressable* and thus shared. In the example you can specify that *count* is addressable, so it is represented within the same heap as all other *int*. This means that an *int* pointer can now point to a plain *int* or to a *count* field within a structure. You explicitly allow this limited inter-type aliasing on *int* pointers. All other fields that are not explicitly marked as *addressable* still have their own heap and thus cannot alias with another pointer of the same field type. Note that mainly for performance reasons we actually avoid to have a separate heap for each single field but try to minimise the number of heaps by clustering the fields that are treated the same. Some more details on this construction are below.

26.21.2 Example Program and some Intuition

We illustrate the approach with the following example specifying some structures, with addressable and non-addressable fields. Note that for an addressable field that is of an array type, each element of the array is considered to be addressable.

install-C-file *open-struct.c*

```
declare [[show-types=false, show-sorts=false,
verbose = 0, verbose-timing = 0, ML-print-depth = 1000, goals-limit = 20]]
```

```
init-autocorres [addressable-fields =
inner.fld1
inner.fld2
outer.inner
outer-array.inner-array
array.elements
other.fy
two-dimensional.matrix
data-struct1.d1.y1
data-struct1.d1.y2
data-struct1.d1.y3
data-struct1.d1.y4
data-struct1.d2
data-struct2.d
data-array.array,
single-threaded ] open-struct.c
```

autocorres *open-struct.c*

Which split heaps are generated? Each split heap is a component of the record *lifted-globals*.

print-record *lifted-globals*

Structure *closed* does not have any addressable field. So there is a separate heap for that component *closed-C*.

Structure *inner* has three *unsigned* fields *fld1-C*, *fld2-C* and *fld3-C*, The first two fields are addressable whereas the third one is not. This means that the first two fields are put into the same common heap for unsigned integers *heap-w32* whereas the third field is stored in a dedicated heap for all remaining fields *dedicated-heap-inner-C*.

We use the following nomenclature to distinguish the various kinds of split heaps and types:

- closed type or structure: There is no addressable field within the type / structure, e.g. *closed-C*.
- open type or structure: There is at least one addressable field within the type / structure, e.g. *inner-C*.
- atomic heap: Heap for a closed type, or a common heap that might be nested in an open structure. e.g. *heap-closed-C*.
- dedicated heap: Internal heap for all non-addressable fields of an open type, e.g. *dedicated-heap-inner-C*. These dedicated heaps are used for the construction of a derived heap.
- derived heap: Heap for an open type / structure. The name 'derived' indicates that it is not a fundamental heap but a composition of several common heaps and a dedicated heap, e.g. *outer-C.inner-C*
- fundamental heap: those heaps that are directly present in the new global state *lifted-globals*. These are atomic heaps, and dedicated heaps.
- virtual heap: heaps that represent the user level view. They are directly visible in the program after heap-lifting. This excludes dedicated heaps, which non-the-less may be used in the model as representation of that type.

Dedicated heaps play a special role, as they are subsumed within derived heaps. In a sense they are not part of the 'API' for split heaps: After heap lifting the resulting program only directly mentions atomic, common or derived heaps. Nevertheless dedicated heaps are important for the construction of derived heaps and might show up after unfolding the definitions for derived heaps.

Also dedicated heaps may be used by the user as the actual heap for a specific type. Only the dedicated heaps and the atomic heaps commute, the derived heaps do not necessary commute with each other as they might have common components that alias each other.

26.21.3 Background

The starting point for the split heap abstraction is still the unified memory model (UMM) by Harvey Tuch (<https://trustworthy.systems/publications/papers/Tuch%3Aphd.pdf>). The UMM provides the general concept of *c-type* to convert between a byte-list representations of C values to abstract HOL-types. It also provides an explicit notion of typing and what a well-typed byte level heap is (with respect to a heap type description). With these notions in place one can describe the set of valid pointers for a C program. The model is quite elaborate and respects the potential nesting of structures. A well-typed pointer to a structure in the heap gives rise to a bunch of other valid sub-pointers, pointing to sub-fields, which again could point to a nested structure. In the UMM, array types are modelled as a special case of a structure, where each index corresponds to an artificial field, where the field name is a unary encoding of the index. Hence, for most of the explanation in this file it is sufficient to elaborate on structures. The main limitation of the UMM is that it does not handle unions.

For the original split heap version of AutoCorres https://trustworthy.systems/publications/nicta_full_text/8758.pdf, David Greenaway put a simplified layer on top of the UMM focusing only on the root-pointers of a structure, ignoring any nested pointers to a field. This provides a split heap abstraction on the granularity of types.

The new split heap model takes an intermediate view. For closed structures it coincides with the original split heap model. Only root-pointers to a closed structure are valid. In addition for open structures also the nested pointers to addressable fields are welcome and valid. This flexibility allows the user to carefully open up the structures only as far as needed. Note the trade-off between expressibility and "proof-burden" of open structures. Aliasing is by construction ruled out for distinct split heaps, but has to be dealt with explicitly on the user level for common heaps.

To allow this flexibility some existing notions were slightly refined and some notions were introduced.

Footprints and valid pointers

The central typing judgement of UMM is *h-t-valid*, with infix syntax $d, g \models_t p$, meaning pointer p is valid with respect to heap type description d and a guard g . The default guard is *c-guard*, ensuring that the pointer is aligned, is

not NULL and that the referenced value fits into the address space, meaning that the addresses of the individual bytes do not overflow the address space. This instantiation with *c-guard* is abbreviated with $d \models_t p$.

thm *c-guard-def*
thm *TypHeap.h-t-valid-def*
thm *h-t-valid-valid-footprint*

The judgement $d, g \models_t p$ also ensures that the footprint is valid: *valid-footprint* d (*ptr-val* p) (*typ-uinfo-t* $TYPE('a)$). Note that p is a typed pointer, carrying the (phantom) type of the value it points to p . This type annotation is no longer present in *valid-footprint* which only talks about the address of the pointer *ptr-val* and relates it to a type tag via *typ-uinfo-t*.

thm *valid-footprint-def*

Without going into details of the definition of *valid-footprint* we get guarantees for all nested pointers of the structure which also have *valid-footprint*. Moreover, what we do not know is whether the pointer p is itself a nested pointer of some enclosing structure.

To get the additional knowledge that term p is a root pointer, meaning it is not enclosed in a bigger structure, we have the notion *valid-root-footprint*. This notion was refined from the original version of AutoCorres *valid-simple-footprint* to get the important property that every *valid-root-footprint* is indeed also a *valid-footprint*.

thm *valid-root-footprint-valid-footprint*

Also for all types that fit into the address space we can go from *valid-root-footprint* to *valid-simple-footprint*. The restriction on the address space size follows from the implicit property of the legacy *valid-simple-footprint*: The first byte and all the rest have a different tag, so there must not be a complete wrap around in the address space.

thm *valid-simple-footprint-size-td*
thm *valid-root-footprint-valid-simple-footprint*

The corresponding judgment to $d \models_t p$ for root pointers is *root-ptr-valid* d p . It implies *c-guard* p as well as *valid-root-footprint* d (*ptr-val* p) (*typ-uinfo-t* $TYPE('a)$).

thm *root-ptr-valid-def*

From byte heap to typed heaps

In UMM the core wrapper functions to provide a typed view on the raw byte level heap are:

- *h-val* to lookup typed values by typed pointers and

- *heap-update* to update the heap on the location designated by a typed pointer with a typed value.

Provided a byte level heap and a heap type description there is a function to lift the heap into a typed heap:

- *lift-t* takes a pointer guard and a pair of byte level heap and heap type description and provides a partial function from typed pointers to typed values. The most prominent instance is abbreviation *clift* = *clift*.

The resulting function is partial as it only lifts those pointers that actually point to valid addresses according to *h-t-valid*. This fact and the connection to *h-val* is reflected in $\text{lift-t } ?g \text{ (?h, ?d)} = (\lambda p. \text{if } ?d, ?g \models_t p \text{ then Some (h-val ?h p) else None})$.

thm *lift-t-if*

To lift root pointers there is

- *simple-lift*. It yields only defined values for root pointers, according to *root-ptr-valid*.

thm *simple-lift-def*

For the derived heaps we introduce the family of functions *plift*, which are defined in *wf-ptr-valid* and instantiated for each collection of open types. Like *clift* the definition is based on *lift-t*, but instead of the plain *c-guard* a custom validity-guard for the type is supplied *PTR-VALID('a)*. The relevant definitions are collected as named theorems:

thm *plift-defs*

Note that we used to introduced a separate distinct instance of *plift* and *PTR-VALID('a)* for each type. Now we have encapsulated this construction in *open-types*. From a specification of which fields of a type should be addressable we first derive an variant without phantom typing of all the concepts especially *open-types.ptr-valid-u* and then define the phantom typed version based on that. This separation works around the limitation of the Isabelle type system that are also reflected in locales. It does not allow explicit quantification on type variables. So we can only have fixed type "variables" in the locale assumptions. However, the lemmas derived within a locale can still be polymorphic. So we express the needed assumptions in the locale *open-types* in the "untyped" world and derive the "typed" polymorphic versions as lemmas within that locale.

thm *open-struct.ptr-valid-u.simps*

thm *open-types.ptr-valid-u.simps*

thm *open-struct.ptr-valid-def*

thm *open-types.ptr-valid-def*

Let us look into the definitions for the open structure *inner-C* which itself is part of the open structure *outer-C*.

lemma *plift h = lift-t (ptr-valid (hrs-htd h)) h*
by (*simp add: open-struct.plift-def*)

thm *inner-C.ptr-valid.unfold*

lemma

fixes *p::inner-C ptr*
shows *ptr-valid d p =*
(root-ptr-valid d p ∨
(∃ q::outer-C ptr. ptr-valid d q ∧ ptr-val p = &(q→["inner-C"])) ∨
(∃ i<5. ∃ q::(inner-C[5]) ptr. ptr-valid d q ∧ ptr-val p = &(q→[replicate i CHR
"1"])))
by (*rule inner-C.ptr-valid.unfold*)

lemma

fixes *p::outer-C ptr*
shows *ptr-valid d p = root-ptr-valid d p*
by (*simp add: ptr-valid*)

A pointer to an *inner-C* is valid according to *PTR-VALID('a) d p*, if it is either

- a root pointer to an *inner-C*, or
- there is a valid pointer to an enclosing pointer *q* to *outer-C*, where *p* is obtained by dereferencing field *"inner-C"*, (Note that valid *outer-C* are already root pointers). or
- there is a valid pointer to an array *q*, where *p* is obtained by indexing into the array. Indexing into arrays is modelled by unary encoded field names *replicate i CHR "1"*. (Note that valid array pointers themselves might have various possible extensions to a root pointer of an enclosing structure)

These pointer-valid predicates are derived from the specification of addressable fields in the corresponding **autocorres** command. They enumerate the possibilities to arrive at a valid pointer starting from a valid root-pointer. The specification is converted to the parameter \mathcal{T} of *open-types*. In our example program this is:

thm *T-def*

The \mathcal{T} is an association list mapping a type tag *typ-uinfo-t* of a *mem-type* to the list of addressable fields within that structure. From this specification we derive a lot of useful notions within the locale. Notably:

thm *ptr-valid* — These go up the chain to the root pointer.

From typed heaps to split heaps

Note that the functions in the previous subsection still are defined on the level of the monolithic UMM memory model. They are central building blocks to finally arrive at the split heap model. Essentially there is a split heap component in the lifted globals corresponding to *plift* for all the fundamental types.

However, instead of partial functions as provided by *wf-ptr-valid.plift* the split heap separates definedness from the actual value, by providing a pair of a total function from pointer to value and a validity predicate which indicates definedness. This design choice was introduced in the original AutoCorres.

As a prerequisite to lift the Functions into the split heap model, the new global state record *lifted-globals* is defined. For each fundamental heap this record contains a field for the split heap e.g. *heap-w32*.

These are the lookup functions provided by the record package, there are of course also the corresponding update functions, e.g.: *heap-w32-update*. Note that the update function behaves like a "map", which maps an update function on the selected heap to an update function on *lifted-globals*.

The typing information (heap type description) is preserved from the monolithic heap in component *heap-typing*.

print-record *lifted-globals*

For the derived heaps we provide a similar abstraction level by defining a derived heap lookup and a derived heap update function. These functions are a composition of the underlying functions for the fields of the structure.

thm *derived-heap-defs*

For example for *outer-C* we have.

- Lookup: *heap-outer-C*
- Pointwise update: *heap-outer-C-map*
- Validity is generically based on the heap typing for all heaps: $\lambda s. IS-VALID('a) s$

Note the difference in the signature of the derived update *heap-outer-C-map* and the fundamental *heap-w32-update*. Besides the difference in naming between 'map' and 'update', the derived update is defined pointwise instead of heap-wide. The reason is that the pointwise update is what we actually need for autocorres and it is natural to break down a pointwise update defined via a function on *f* to the update functions on the fields of *outer-C*.

thm *heap-outer-C-def*

thm *heap-outer-C-map-def*

The connection between *globals* (containing the byte level heap) and *lifted-globals* is defined via the function *lift-global-heap*. The fundamental heaps are lifted via the corresponding *wf-ptr-valid.plift* functions. Validity of pointers is maintained by literally preserving the heap typing from the monolithic heap.

thm *lift-global-heap-def*

thm *lift-t-def*

thm *plift-defs*

26.21.4 User Level

Due to the abstraction layer of derived heap types, the structure of the programs after heap lifting is analogous for closed and opened structures.

context *ts-definition-set-c1*

begin

thm *ts-def*

lemma *set-c1' p c* \equiv *do* {*guard* (λs . *IS-VALID*(*closed-C*) *s p*);

modify (*heap-closed-C-update* (λh . *h*(*p* := *c1-C-update* (λ -. *c*) (*h*

p))))

}

by (*rule ts-def*)

end

context *ts-definition-outer-fld1-upd*

thm *ts-def*

end

Of course, when it comes to specifications and proving properties about the programs, the user has to take care about aliasing of addressable fields. *AutoCorres* generates a bunch of theorems and sets up the simpsets with some obvious rules for derived heaps, which hopefully helps in doing so. However, as a last resort one might still have to unfold the definitions and

work with the parts. Here is some examples of some theorems or collections of theorems.

addressable-fields, merge-addressable-fields, read-dedicated-heap, write-dedicated-heap

We distinguish three aspects when thinking and reasoning about split heaps: the monolithic heap stored in *globals* the split heap components in *lifted-globals* and the function *lift-global-heap* which transforms between both types. Autocorres does a refinement proof that a program operating on *lifted-globals* refines a program on *globals* where the heaps are related by function *lift-global-heap*.

For open structures, the fields which are addressable have two representations in *lifted-globals*:

1. the relevant value in the common heap, i.e. *heap-w32* for the *inner.fld1* pointers
2. an unused value in the field of the dedicate heap, i.e. the *fld1-C* in the *dedicated-heap-inner-C*. Having the dedicated heap allows us to keep all non-addressable fields of a structure in a single split heap component of *lifted-globals*. The values of the addressable fields are irrelevant

for the virtual heap. When reading from a virtual heap we start with the value in the dedicated heap and overwrite the addressable fields by considering the common heaps.

thm *heap-inner-C-def*

When writing to a virtual heap we have a series of updates on *lifted-globals*. We start by updating the non-addressable fields in the dedicated heap and then updating the common heaps with the new values for the addressable fields:

thm *heap-inner-C-map-def*

To express "update the non-addressable fields of the dedicated heap" in an uniform way we make use of the concept of *scenes* from the world of *lenses*. In contrast to lenses, scenes are formalised by properties of a single function $'a \Rightarrow 'a \Rightarrow 'a$ which is referred to as *merge* or 'overrider' operation. The intuition of *merge* $x y$ is that we take certain portions of a compound value x and merge (or override) them into another compound value y . Scenes are formalised in locale *is-scene*. The notion *merge* emphasises the symmetric nature of the merge operation. Like a lense, a scene 'focuses' on a portion of a compound value $'a$. The merge operation takes that portion from the first argument and the complement of that portion from the second argument. Think for example of a pair and the 'portion' being the first component. Then $merge\ x\ y = (fst\ x,\ snd\ y)$. The notion *overrider* puts more emphasis on the merge as an update function, in particular this view becomes obvious if we think of a partial application *merge* x : this is an update function which overrides the 'portion' within an value y to that portion of x . You can also think of fixing the 'portion' to those values in x . Analogously $\lambda x. merge\ x\ y$ fixes the complement of the 'portion' to those values in y . Scenes are closely related to lenses in the sense that it is straightforward to derive a scene from a lense $lense\ ?r\ ?w \implies is-scene\ (\lambda a. ?w\ (\lambda-. ?r\ a))$.

thm *is-scene-of-lense*

For HOL the decisive advantage of scenes compared to lenses is that they only have one type parameter, which fixes the type of the compound value. But still you can formally 'talk' about different 'portions' of that value in an uniform way. For example you can have a list or a set of scenes to describe their composition. This property can be used to uniformly describe "all addressable fields" of a value or "all non-addressable fields" of a value.

The relevant merging function for us is *merge-addressable-fields* which is an abbreviation $\lambda \mathcal{T}. merge-ti-list\ (map\ snd\ (open-types.addressable-fields\ \mathcal{T}\ TYPE('a)))$.

term $\langle open-types.merge-addressable-fields \rangle$

The term *merge-addressable-fields* $old\ new$ has to effects:

- The addressable fields are taken from *old*
- The non-addressable fields are taken from *new*.

To express the same semantics that we have just described for *lifted-globals* on the UMM heap in *globals* we make use of the functions *read-dedicated-heap* and *write-dedicated-heap*. These functions internally again make use of *merge-addressable-fields*. We zero out all parts of the compound value we are not actually interested in. This gives us canonical values which we can easily relate to the *lifted-globals*. For example for *read-dedicated-heap* we zero out all addressable fields and also all values which are not even *PTR-VALID('a)* (according to *plift*).

lemma (in *open-types*)

read-dedicated-heap *h p* =
merge-addressable-fields *ZERO('a::mem-type)* (*the-default ZERO('a)* (*plift h p*))
by (*simp add: read-dedicated-heap-def*)

thm *open-types.read-dedicated-heap-def*

thm *open-types.write-dedicated-heap-def*

The lifting function *lift-global-heap* directly uses *read-dedicated-heap* to construct a dedicated heap from the UMM heap:

thm *lift-global-heap-def*

To have a canonical representation we overwrite the fields in the dedicated heap with zeros, using the generic constants *addressable-fields* and *merge-addressable-fields* defined in *open-types*.

read-dedicated-heap, write-dedicated-heap combine these with *h-val*, to get the canonical heap access.

Why all the variants? *h-val* / *read-dedicated-heap*

thm *lifted-globals-ext-simps*

thm *lift-global-heap-def*

thm *open-types.read-dedicated-heap-def*

When taking a close look in the definition of *lift-global-heap* one sees that the abstraction for a split heap component from the monolithic heap is:

read-dedicated-heap (*t-hrs-' g*)

So this might seem a bit surprising at first sight. What is all the indication useful for:

1. the *read-dedicated-heap* adds an option layer to the plain *h-val* and *plift*

2. with *t-hrs-'* we get the heap representation (including bytes and types)

When we know that a pointer is valid there is a tight connection between *read-dedicated-heap* and *h-val*

thm *open-struct.ptr-valid.ptr-valid-plift-Some-hval*

thm *open-struct.read-dedicated-heap-def*

This connection directly carries over to lifting.

thm *read-commutes*

The difference between *read-dedicated-heap* and *h-val* becomes apparent when looking at partial heaps and invalid pointers. While *read-dedicated-heap* always yields *ZERO('a)* the plain *h-val* will still construct some value out of the bytes in the heap. So in a sense the indirection to *read-dedicated-heap* makes heaps equal if they agree on the valid pointers only. So we encode "heap equality only on valid pointers" in an ordinary equality on the complete lifted heap. This choice ensures compositionality for the polymorphic *ZERO('a)*, in the sense that the *ZERO('a)* of a structure means that all subcomponents are *ZERO('a)*.

Moreover *read-dedicated-heap* only reads the fields which are not addressable, and overwrites the addressable fields with *ZERO('a)*. This gives us a canonical view on the partial heap.

thm *zero-simps*

thm *open-struct.ptr-valid.plift-None*

I miss the typing in the split heap!

A peculiar property of the original split heap model of autocorres was that you lose parts of the type information that were directly available in the byte-level heap. There was no heap-type description in *lifted-globals* but only the more abstract *is-valid-<type>* fields for each type. For closed types this isn't so much of an issue as essentially all relevant type information is captured in the fact that all pointers to that type have a distinct split heap, which is separate from all other split heaps. But for shared types this is no longer true. Thus we maintain the typing information also in the split heap in the component *heap-typing*. The relation to the typing information of the original byte-level heap is encapsulated in *lift-global-heap*. For low-level operations that are embedded via *exec-concrete* you can directly connect the typing of the monolithic and the split heap. In particular you can derive *c-guard p* from that information. Or you can derive that if you have two valid pointers of the same type, where you only know that the address is different, you can still conclude that the complete pointer span of the pointers do not overlap.

But keep in mind that typing is only a "discipline". As in the split heap you can manipulate the values on the heap or split heap indepen-

dent of the typing information. When well-typedness or $PTR-VALID('a)$ is available you might be able to derive properties like distinctness of pointer spans. The distinctness of pointers spans is the actual reason that certain heap updates commute, e.g. $disjnt (ptr-span ?p) (ptr-span ?q) \implies heap-inner-C-map ?q ?g (heap-inner-C-map ?p ?f ?s) = heap-inner-C-map ?p ?f (heap-inner-C-map ?q ?g ?s)$

thm *heap-inner-C.write-other-commute*

26.21.5 Simulation Proof

The simulation of a concrete program C operating on the byte-level heap by an abstract program A operating on the split heaps is captured in predicate $L2Tcorres\ lift-global-heap\ A\ C$. The proof for an instance of C follows the syntactic structure of C by applying introduction rules and synthesizing the abstract program A .

Intuitively the core properties on which the simulation proof builds are:

- Abstract programs only operate on abstract heap values not on byte-lists. Byte-level concepts like padding fields are irrelevant for the abstract program. The abstract heaps and programs don't distinguish between two byte-level heaps if they agree on all values of non-padding fields of properly allocated and typed portions of the heap.
- Lookup and update via a pointer into a structure can be simulated by an lookup and update via the root pointer of the structure.
- Each non-addressable field of a structure is mapped into exactly one split heap. For a 'closed' structure without any addressable fields this is the heap for the type.
- For an 'open' structure an addressable field is mapped into a shared heap or multiple shared heaps in case the field is again an open structure.
- The pointer spans of two valid root pointers of different types do not overlap.
- The pointer spans of two valid root pointers to the same type might overlap only if the pointer value is the same.

The actual proof of a simulation is divided into three main steps.

- First some general theorems relating byte-level and split heaps are derived. Most prominently *typ-heap-simulation* and related predicates.
- These theorems are used to instantiate the syntax driven introduction rules collected in named theorems $\llbracket abs-expr\ ?st\ ?X\ ?f1.0\ ?f1'\ ;\ abs-expr$

$\llbracket ?st \ ?Y \ ?f2.0 \ ?f2 \rrbracket \Longrightarrow \text{abs-expr } ?st \ (\lambda s. \ ?X \ s \wedge \ ?Y \ s) \ (\lambda s. \ (?f1.0 \ s, \ ?f2.0 \ s)) \ (\lambda s. \ (?f1' \ s, \ ?f2' \ s))$

- First some normalisation of expressions involving pointers is performed on the concrete program C . In particular an update to a dereferenced pointer $\&(p \rightarrow f)$ by a value v is transformed to an update on p , where first the value of p is fetched from memory and then field f of this value is updated by v and the resulting compound value is put back to memory.
- Only after the normalisation on C , the actual translation to an abstract A on the split heap is performed.

The normalisation step is guided by predicates *struct-rewrite-guard*, *struct-rewrite-expr* and *struct-rewrite-modifies*. After that normalisation the atomic building block for the simulation is provided by an instance of *typ-heap-simulation*, which tells how a lookup and update of a pointer of a given type in the byte heap is simulated in the split heap.

The proofs of the necessary instances of *typ-heap-simulation* are provided once and for all in the initialisation phase of **autocorres** or **init-autocorres**. They are provided for atomic and shared heaps as well as derived heaps.

Proving *typ-heap-simulation*

As stated before this step was extended quite excessively and quite some infrastructure of both theorems as well as ML code were built to support it.

Typed vs. Untyped Dialects/ Records vs. Byte-Lists First some general remarks on the general concepts and setup. The UMM was designed in the spirit to take advantage of HOL type and class inference to support reasoning about C-types and pointers. As a consequence some of the definitions and theorems are rather subtle and somehow live on the edge of what can be typed and expressed in the HOL type system. Sometimes the essence or the limitations of a theorem only become 'visible' when also looking at the types of expressions, especially the pointer types. Unfortunately writing about these concepts is rather ambiguous with respect to the notion type. 'Type' might refer to the original C-structure in the C program, this type is related to an abstract HOL-type, which is a record. This record is an instance of various type-classes: *c-type*, *mem-type*, *xmem-type*. For types of *c-type* we define overloaded *typ-info-t*, which associates a HOL-term describing the type (referred to as type-description or type-information). Moreover, pointers represented in HOL carry the HOL-type they point to as phantom type.

An illustration for the subtle typing is the two terms $\&(p \rightarrow f) \neq \&(q \rightarrow g)$ vs. $p \neq q \implies \&(p \rightarrow f) \neq \&(q \rightarrow g)$. Whereas in first term the pointers p and q have a different type, in the second term they both have the same type as the inequation in the precondition also makes the types equal. This might not always be the intended meaning. When the type of the pointer is irrelevant one might resort to plain addresses instead of pointers $ptr\text{-}val\ p = ptr\text{-}val\ q \implies \&(p \rightarrow f) = \&(q \rightarrow g)$. This general theme occurs in various places. There often is a typed variant of a concept and also an untyped variant, based on addresses or byte lists, like p vs. $ptr\text{-}val\ p$. Both are closely related. The typed variant somehow reflects the 'API' of the concept and is more abstract, whereas during a proof one actually resort to the untyped variant to gain flexibility. These two views on a concepts leads to a duplication of lemmas. Moreover, a lemma might not immediately be available in the form one expects, but can be 'easily' derived from some related lemmas.

The central UMM HOL-datatype to reflect C-types into HOL terms is $(\prime a, \prime b)\ typ\text{-}desc$ and is defined mutually recursive with $(\prime a, \prime b)\ typ\text{-}struct$. It

is basically a tree describing the nested structure of an aggregate type. Field names, alignment and size information is encoded, and lookup and update of sub-fields can be derived from this information.

The most prominent instances of this type are the typed variant *'a xtyp-info* vs. the untyped variant *typ-uinfo*. The former can be transformed to the latter by *export-uinfo*. As with pointer types the type variable in *'a xtyp-info* denotes the abstract HOL-C-type that is described by the type information. So to derive a field-lookup or field-update on HOL-types from the type information one needs to resort to the typed variant. Exporting the type information via *export-uinfo* maintains the shape of the tree, but removes all the HOL-C-type dependent components. The resulting *typ-uinfo* has two main use cases:

- It can be seen as a type-tag identifying a C-type. It can be used to relate two C-types on the HOL-term level, e.g. ask if they are equal or if one is contained in the other.
- It can be used to normalise a byte-list representing a value of that type. Normalisation means that all padding bytes in the byte-list are set to zero.

For each C-type the C-Parser also generates the type information which can be accessed via the overloaded function: *typ-info-t TYPE('a)*.

The main use cases for *typ-info-t TYPE('a)* are

- Provide lenses for fields (access / update) on the abstract value (record), via *access-ti*, *update-ti* and *field-lookup* The main use cases for *typ-uinfo-t TYPE('a)* are
- comparison of type descriptors: equality and order $s \leq_{\tau} t$
- normalisation of byte-lists *norm-tu*, in particular setting all padding bytes to zero.

thm *sub-typ-def*

thm *typ-tag-le-def*

So *typ-info-t* is more related to the abstract view on a value (as a HOL record), whereas *typ-uinfo-t* is more related to the byte-list encoding of the value. This duality somehow also reflects the dual nature of types in C. On the one hand C is a statically typed language and on the other hand it allows to break the abstraction and switch to a low-level byte oriented view.

context

fixes *p::'a::c-type ptr*

fixes *f::qualified-field-name*

fixes *t::'a xtyp-info*

fixes $n:: \text{nat}$
begin

A central function on both typed and untyped typ-information is the function *field-lookup* which retrieves the type-information for a field of a type. A common application of this function is to state some property on a dereferenced pointer: $\text{PTR}('b) \ \&(p \rightarrow f)$. Note that p is an pointer to an ' a ': p . A typical precondition is to retrieve the type-information for field f from the type information of ' a ': $\text{field-lookup}(\text{typ-info-t TYPE}('a)) \ f \ 0 = \text{Some}(t, n)$

Note that the retrieved type information t is still tagged with ' a '. The number n is the offset of the selected field. Typically we want to relate t to the type of the selected field ' b ' (which only happens to be the same ' a ' in case the field is the empty list). The relation can be established via *export-uinfo*, namely $\text{export-uinfo} \ t = \text{export-uinfo}(\text{typ-info-t TYPE}('b))$. Note that directly equating t to $\text{typ-info-t TYPE}('b)$ is not even a well-typed expression in HOL, as ' a ' is not equal to ' b '.

The right hand side abbreviates to constant $\text{typ-uinfo-t TYPE}('b)$.

end

A concrete example might give some further insight to the relation of *typ-info-t* and *typ-uinfo-t* and how the type-information is constructed. Let us consider the field "*inner-C*" of *outer-C*, which selects a field of *inner-C*. We can retrieve the information for the field:

lemma $\text{field-lookup}(\text{typ-info-t TYPE}(\text{outer-C})) \ [\"inner-C\"] \ 0 =$
 $\text{Some}(\text{adjust-ti}(\text{typ-info-t TYPE}(\text{inner-C})) \ \text{outer-C.inner-C} \ (\text{inner-C-update} \circ$
 $(\lambda x \ . \ x)), \ 0)$
by *(simp)*

Note that the retrieved type information is constructed from the nested type information for *inner-C*, by adjusting it. Adjusting means that we say how we can lookup and update the sub-field of the record *outer-C*. This adjustment only affects the typed-view of the type information. Exporting the type information collapses to the adjusted inner type:

lemma $\text{export-uinfo}(\text{adjust-ti}(\text{typ-info-t TYPE}(\text{inner-C})) \ \text{outer-C.inner-C} \ (\text{inner-C-update}$
 $\circ (\lambda x \ . \ x)))$
 $= \text{export-uinfo}(\text{typ-info-t TYPE}(\text{inner-C}))$
by *simp*

In the realm of 'lenses', *adjust-ti* can be viewed as a form of composition of lenses. A lense for an inner type is transformed to a lense on the outer type. The lense associated to type information is captured in *access-ti*, for the 'lense-lookup' aka. 'lense-get' part, and *update-ti* for the 'lense-update' aka 'lense-put'.

Function *field-lookup* is the essential building block to relate field names e.g. as part of dereferencing a pointer to their abstracts operations on the

associated HOL-type. One can convert between the typed and untyped version:

thm *field-lookup-export-uinfo-Some-rev*
thm *field-lookup-export-uinfo-Some*

Here are some closely related, mostly derived concepts around *field-lookup*:

- *field-lookup*, *field-ti*, *field-offset*, *field-of*
- *td-set*, *sub-typ* ($s \leq_{\tau} t$)
- Family of field name functions: *all-field-names*, *TypHeap.field-names*, *field-names-u*, *field-names-no-padding*, *all-field-names-no-padding*

Often lemmas might not be available for all variants, but via some simple indirections, via definitions or conversion lemmas. In an Isar-proof, **sledgehammer** can often help to find the connections.

Doing the Proof The fundamental goal is to derive interpretations *typ-heap-simulation* for every relevant type. It states that the virtual heap for a type as obtained from *lifted-globals* simulates the original UMM heap in *globals*. Both states are connected by the abstraction function *lift-global-heap* which is the abstract function *st* in *typ-heap-simulation*. To facilitate the construction of the proofs we introduce intermediate helper locale *typ-heap-simulation-open-types* and make use of the infrastructure of lenses and scenes that we mentioned before.

To optimize the construction (in particular to minimise the number of heaps we have to put into into *lifted-globals*) we distinguish three main cases:

- A structure is closed and has no addressable fields: $\llbracket \text{open-types } ?\mathcal{T}; \text{heap-typing-simulation } ?\mathcal{T} \text{ ?hrs ?hrs-upd ?heap-typing ?heap-typing-upd } ?l; \text{lense } ?R \text{ ?u}; \text{map-of } ?\mathcal{T} (\text{typ-uinfo-t TYPE}(?'a)) = \text{None}; \bigwedge p \ x \ s. \text{open-types.ptr-valid } ?\mathcal{T} (\text{hrs-htd } (?hrs \ s)) \ p \implies ?l \ (?hrs-upd (\text{open-types.write-dedicated-heap } ?\mathcal{T} \ p \ x) \ s) = ?u \ (\text{upd-fun } p \ (\lambda \text{old. merge-ti-list } (\text{map snd } (\text{open-types.addressable-fields } ?\mathcal{T} \ \text{TYPE}(?'a))) \ \text{old } x)) \ (?l \ s); \bigwedge x \ d \ h. \ ?\text{heap-typing-upd } d \ (?u \ x \ h) = ?u \ x \ (?heap-typing-upd \ d \ h); \bigwedge p \ s. \forall a \in \text{ptr-span } p. \text{root-ptr-valid } (\text{hrs-htd } (?hrs \ s)) \ (\text{PTR}(\text{stack-byte } a)) \implies ?R \ (?l \ s) \ p = \text{ZERO}(?'a); \bigwedge h \ p. \ ?V \ h \ p = \text{open-types.ptr-valid}$

$?T$ ($?heap\text{-}typing$ h) p ; $\wedge p f h. ?W p f h = ?u (\lambda h'. h'(p := f (h' p)))$
 $h\]] \implies typ\text{-}heap\text{-}simulation\text{-}open\text{-}types ?T ?l ?R ?W ?V ?hrs ?hrs\text{-}upd$
 $?heap\text{-}typing ?heap\text{-}typing\text{-}upd$ In this case there is only one relevant
heap in *lifted-globals*. No overlay of a dedicated heap with some com-
mon heaps is necessary.

- A structure is completely open, meaning that all fields are addressable:
 $\llbracket open\text{-}types ?T; heap\text{-}typing\text{-}simulation ?T ?hrs ?hrs\text{-}upd ?heap\text{-}typing$
 $?heap\text{-}typing\text{-}upd ?l; map\text{-}of ?T (typ\text{-}uinfo\text{-}t TYPE(?a)) = Some ?fs;$
 $length ?rs = length ?fs; length ?ws = length ?fs; list\text{-}all (\lambda(f, r, w).$
 $open\text{-}types.typ\text{-}heap\text{-}simulation\text{-}of\text{-}field ?T ?l ?hrs ?hrs\text{-}upd ?heap\text{-}typing\text{-}upd$
 $f r w) (zip ?fs (zip ?rs ?ws)); distinct\text{-}prop (\lambda(f1, w1) (f2, w2). disj\text{-}fn$
 $f1 f2 \longrightarrow pointer\text{-}writer\text{-}disjnt\text{-}eq w1 w2) (zip ?fs ?ws); \wedge a b. fold$
 $(\lambda x. merge\text{-}ti (the (field\text{-}ti TYPE(?a) x)) a) ?fs b = a; \wedge h p. ?V h$
 $p = open\text{-}types.ptr\text{-}valid ?T (?heap\text{-}typing h) p; \wedge h p x. ?R h p =$
 $fold (\lambda r. r h p) ?rs x; \wedge p f h. ?W p f h = fold (\lambda w. w p (f (?R$
 $h p))) ?ws h\]] \implies typ\text{-}heap\text{-}simulation\text{-}open\text{-}types ?T ?l ?R ?W ?V$
 $?hrs ?hrs\text{-}upd ?heap\text{-}typing ?heap\text{-}typing\text{-}upd \wedge (\forall w. (\forall x. list\text{-}all (\lambda w'.$
 $pointer\text{-}writer\text{-}disjnt (\lambda p. w' p x) w) ?ws) \longrightarrow (\forall f. pointer\text{-}writer\text{-}disjnt$
 $(\lambda p. ?W p f) w)) \wedge (\forall w p. (\forall x. list\text{-}all (\lambda w'. w' p x \circ w = w \circ w'$
 $p x) ?ws) \longrightarrow (\forall f. ?W p f \circ w = w \circ ?W p f))$. In this case we do
not need a dedicated heap. The structure is described by a overlay of
common heaps.
- A structure is partially open, some fields are addressable and some not:
 $\llbracket open\text{-}types ?T; heap\text{-}typing\text{-}simulation ?T ?hrs ?hrs\text{-}upd ?heap\text{-}typing$
 $?heap\text{-}typing\text{-}upd ?l; map\text{-}of ?T (typ\text{-}uinfo\text{-}t TYPE(?a)) = Some ?fs;$
 $lense ?g ?u; length ?rs = length ?fs; length ?ws = length ?fs; list\text{-}all$
 $(\lambda(f, r, w). open\text{-}types.typ\text{-}heap\text{-}simulation\text{-}of\text{-}field ?T ?l ?hrs ?hrs\text{-}upd$
 $?heap\text{-}typing\text{-}upd f r w) (zip ?fs (zip ?rs ?ws)); distinct\text{-}prop (\lambda(f1,$
 $w1) (f2, w2). disj\text{-}fn f1 f2 \longrightarrow pointer\text{-}writer\text{-}disjnt\text{-}eq w1 w2) (zip$
 $?fs ?ws); list\text{-}all (\lambda w. \forall p a f. w p a \circ ?u f = ?u f \circ w p a) ?ws;$
 $\wedge p x s. open\text{-}types.ptr\text{-}valid ?T (hrs\text{-}htd (?hrs s)) p \implies ?l (?hrs\text{-}upd$
 $(open\text{-}types.write\text{-}dedicated\text{-}heap ?T p x) s) = ?u (upd\text{-}fun p (\lambda old.$
 $merge\text{-}ti\text{-}list (map snd (open\text{-}types.addressable\text{-}fields ?T TYPE(?a)))$
 $old x)) (?l s); \wedge p s. \forall a \in ptr\text{-}span p. root\text{-}ptr\text{-}valid (hrs\text{-}htd (?hrs s))$
 $(PTR(stack\text{-}byte) a) \implies ?g (?l s) p = ZERO(?a); \wedge x d h. ?heap\text{-}typing\text{-}upd$
 $d (?u x h) = ?u x (?heap\text{-}typing\text{-}upd d h); \wedge h p. ?V h p = open\text{-}types.ptr\text{-}valid$
 $?T (?heap\text{-}typing h) p; \wedge h p. ?R h p = fold (\lambda r. r h p) ?rs (?g h p); \wedge p$
 $f h. ?W p f h = fold (\lambda w. w p (f (?R h p))) ?ws (?u (upd\text{-}fun p (\lambda old.$
 $merge\text{-}ti\text{-}list (map snd (open\text{-}types.addressable\text{-}fields ?T TYPE(?a)))$
 $old (f (?R h p)))) h\]] \implies typ\text{-}heap\text{-}simulation\text{-}open\text{-}types ?T ?l ?R$
 $?W ?V ?hrs ?hrs\text{-}upd ?heap\text{-}typing ?heap\text{-}typing\text{-}upd \wedge pointer\text{-}lense$
 $?g (\lambda p f. ?u (upd\text{-}fun p f)) \wedge (\forall w. (\forall x. list\text{-}all (\lambda w'. pointer\text{-}writer\text{-}disjnt$

$(\lambda p. w' p x) w) ?ws) \longrightarrow (\forall x. \text{pointer-writer-disjnt } (\lambda p. ?u (\text{upd-fun } p (\lambda-. x))) w) \longrightarrow (\forall f. \text{pointer-writer-disjnt } (\lambda p. ?W p f) w) \wedge (\forall w p. (\forall x. \text{list-all } (\lambda w'. w' p x \circ w = w \circ w' p x) ?ws) \longrightarrow (\forall x. ?u (\text{upd-fun } p (\lambda-. x)) \circ w = w \circ ?u (\text{upd-fun } p (\lambda-. x))) \longrightarrow (\forall f. ?W p f \circ w = w \circ ?W p f))$. In that case we need an overlay of a dedicated heap and some common heaps.

On an intuitive abstract level the lemmas and proof argue about composing field-level lookup and updates within some heap(s) to lookup and updates of the complete compound structure. We want to argue that lookup and update in the UMM heap is simulated by the overlaid updates of a dedicated heap and some common heaps in the split heap. To argue about different fields of a structure we build on the idea of scenes and also extend it to reads. Note that the general problem is that a structure is represented as a HOL record and each field has a distinct type. Because of the limitations of the HOL type system we cannot directly combine e.g. functions like readers for different fields like $'a \Rightarrow 'b1$ and $'a \Rightarrow 'b2$ in a HOL list. Here the scene idea to express everything via a merge or update on $'a$ is a helpful 'trick'. E.g. 'reading' the value of a field can in a sense be as well expressed as a function $'a \Rightarrow 'a \Rightarrow 'a$ that reads the field of the first argument and puts it into any structure you give it as second argument:

thm *lift-global-heap-def*
thm *open-types.typ-heap-simulationI-all-addressable*
thm *open-types.typ-heap-simulationI-part-addressable*
thm *open-types.typ-heap-simulationI-no-addressable*
thm *pointer-lense-def*
thm *partial-pointer-lense-def*
thm *typ-heap-simulation-of-field-def*

Other important building blocks are:

- *pointer-lense* which describes a virtual heap.
- *partial-pointer-lense* which describes the effect of field lookup / updates on a virtual heap by combining a scene identifying the field and the pointer lense for the virtual heap.
- *typ-heap-simulation-of-field* $?st ?t\text{-hrs} ?t\text{-hrs}\text{-update} ?\text{heap}\text{-typing}\text{-upd} ?f' ?r' ?w' = ((\forall d p f. ?\text{heap}\text{-typing}\text{-upd } d \circ ?w' p f = ?w' p f \circ ?\text{heap}\text{-typing}\text{-upd } d) \wedge (\forall t u n. \text{field-ti } \text{TYPE}('a) ?f' = \text{Some } t \longrightarrow \text{field-lookup } (\text{typ-uinfo-t } \text{TYPE}('a)) ?f' 0 = \text{Some } (u, n) \longrightarrow \text{partial-pointer-lense } (\text{merge-ti } t) ?r' ?w' \wedge (\forall p s. (\forall a \in \text{ptr-span } p. \text{root-ptr-valid } (\text{hrs-htd } (?t\text{-hrs } s)) (\text{PTR}(\text{stack-byte } a)) \longrightarrow ?r' (?st s) p \text{ZERO}('a) = \text{ZERO}('a)) \wedge (\forall p x h. \text{ptr-valid-u } u (\text{hrs-htd } (?t\text{-hrs } h)) \&(p \rightarrow ?f') \longrightarrow ?st (?t\text{-hrs}\text{-update } (\text{hrs-mem}\text{-update } (\text{heap-upd-list$

$(\text{size-td } u) \ \&(p \rightarrow ?f') \ (\text{access-ti } t \ x)) \ h) = ?w' \ p \ x \ (?st \ h))$ which is used to break down *typ-heap-simulation* to the level of fields in the structure.

The automation is implemented in `HeapLiftBase.gen_new_heap`.

The following paragraphs describe some abstract arguments and lemma collections. In a previous version the proof *typ-heap-simulation* was more directly based on those arguments implemented in ML. Meanwhile we were able to replace most parts of the ML code by lemmas described before based on scenes and pointer lenses. Nevertheless the arguments are still valid and the lemma collections might be useful in other places.

Fundamental heaps We start with the fundamental heaps. The simulation property for heap-updates is captured in *write-simulation*. It is a commutation property. Provided we have a valid pointer in the split heap (obtained from lifting from the byte-level heap), we can either first perform the heap update in the byte-level heap and then lift the state via *lift-global-heap*, or first lift the byte-level heap into the split heap and apply the corresponding update there. Both ways yield the same final state. So we have to prove equality of two states of *lifted-globals*. The first question is which parts of the state did change? Intuitively only the affected split heap did change, all other heaps stayed the same. But all split heaps are derived from the same byte level heap. So the proof decomposes into two main arguments, one is for the affected heap where we have to show that both updates, the one on the byte-level heap and and the one on the affected split heap, are the same. The other argument is that all other split heaps remain unchanged. Actually the first case is the more straight forward one and could be handled with theorems like $PTR\text{-}VALID(?a) \ (\text{hrs-htd } ?h) \ ?p \Longrightarrow \text{plift} \ (\text{hrs-mem-update} \ (\text{heap-update } ?p \ ?v) \ ?h) = (\text{plift } ?h)(?p \mapsto ?v)$.

thm *plift-heap-update*

The second case, to prove what is not changed is more involved. As a split heap might not only contain root pointers but also valid pointers that are nested in other types we have to distinguish several cases. We developed a general theory in *open-types* and the essential theorems for the commutation proof are collected in $\llbracket PTR\text{-}VALID(?a) \ ?d \ ?p; PTR\text{-}VALID(?a) \ ?d \ ?q \rrbracket \Longrightarrow h\text{-val} \ (\text{heap-update } ?p \ ?v \ ?h) \ ?q = ((h\text{-val } ?h)(?p := ?v)) \ ?q$

$\llbracket PTR\text{-}VALID(?a) \ ?d \ ?p; PTR\text{-}VALID(?a) \ ?d \ ?q; \text{length } ?bs = \text{size-of } TYPE(?a) \rrbracket \Longrightarrow h\text{-val} \ (\text{heap-update-padding } ?p \ ?v \ ?bs \ ?h) \ ?q = ((h\text{-val } ?h)(?p := ?v)) \ ?q$

$PTR\text{-}VALID(?a) \ (\text{hrs-htd } ?h) \ ?p \Longrightarrow \text{plift } ?h \ ?p = \text{Some} \ (h\text{-val} \ (\text{hrs-mem } ?h) \ ?p)$. When we update the heap at pointer p and lookup the value of pointer q we can distinguish various cases by analysing the type relation

(e.g. if one type is nested in the other). Note that by introducing guards into the code and the design of *lift-global-heap* we only have to care about the case where both pointers are valid according to $PTR-VALID('a)$. To be more specific. That the pointer that is updated is $PTR-VALID('a)$ is ensured by the corresponding guard on the update. That the pointer we read from is actually $PTR-VALID('a)$ is more subtle. Here we rely on the construction of *lift-global-heap* where a split heap is constructed by $\lambda p. the-default\ ZERO('a)\ (plift\ (t-hrs-' g)\ p)$. In case the pointer is invalid we always obtain $ZERO('a)$ and hence only the valid pointers may be affected by an heap update. This reduction to valid pointers and $h-val$ is encapsulated in theorems $root-ptr-valid\ (hrs-htd\ ?h)\ ?p \implies the-default\ ZERO(?'a)\ (simple-lift\ (hrs-mem-update\ (heap-update\ ?p\ ?v)\ ?h)\ ?q) = ((\lambda p. the-default\ ZERO(?'a)\ (simple-lift\ ?h\ p)))(?p := ?v)\ ?q$

Treatment of Array Types At the core there is no special type-information for array types. It is treated analogously to structures. Each index gets an individual field name which is the unary encoding of the index. The good thing is that one does not need any new fundamental lemmas to deal with array types. But it is not a good idea to unfold the type-information for arrays and to work on that expanded version. On the one hand things like simplification might become slow, on the other hand we can make use of the regular structure of array types and once and for all derive general lemmas.

The central theorems to work with field-lookup in arrays are $?n < \text{CARD}(?b) \implies \text{field-lookup } (\text{typ-info-t } \text{TYPE}(?a[?b])) [\text{replicate } ?n \text{ CHR}$

"1'" $?i = \text{Some } (\text{adjust-ti } (\text{typ-info-t } \text{TYPE}(\text{'a})) (\lambda x. x.[?n]) (\lambda x f. \text{Arrays.update } f \text{'n } x), ?i + ?n * \text{size-of } \text{TYPE}(\text{'a}))$ and $?i < \text{CARD}(\text{'b}) \implies \text{array-ptr-index } ?p \text{ False } ?i = \text{PTR}(\text{'a}) \ \&(\text{'p} \rightarrow [\text{replicate } ?i \text{ CHR "1"}])$.
The latter one allows to convert between an array-index-arithmetic based view of array pointers $\text{array-ptr-index } p \text{ False } i$ and the field-name view $\text{PTR}(\text{'a}) \ \&(p \rightarrow [\text{replicate } i \text{ CHR "1"}])$.

thm *field-lookup-array*

thm *array-ptr-index-field-lvalue-conv*

These theorems are used to normalise array accesses towards symbolic field name accesses of the format term $\text{Ptr } \&(p \rightarrow [\text{replicate } i \text{ CHR "1"}])$. Note that we don't unfold the definition of *replicate* here, and index i stays abstract, constrained by precondition that limits its range.

thm *unpacked-C.ptr-valid.unfold*

thm *unpacked-C'array-2.ptr-valid.unfold*

The instances of *typ-heap-simulation* can be established from *typ-heap-simulation* of the element types. We introduce the locales *array-heap-simulation* and *two-dimensional-array-heap-simulation* to automatically provide the sublocale relations when the element type falls into *array-outer-max-size* or *array-inner-max-size* respectively.

Derived Heaps The commutation proofs for derived heaps follow another path. For derived heaps we can assume that we have all the instances of *typ-heap-simulation* of the component types already available. Unaddressable fields are never shared. Pointers only appear within a dedicated enclosing parent structure. Validity of the pointer coincides with validity of the parent pointer. Pointers that are mapped by the field heap coincide with the parent pointers, there is no need to calculate the offset of the field. So deriving the commutation proof from the available theorems boils down to their composition. The central lemma connects an update of a derived heap to an fold over the updates of the toplevel fields: $c\text{-guard } ?p \implies \text{heap-update } ?p \ ?x = \text{heap-update } (\text{PTR}(32 \text{ word}) \ \&(\text{'p} \rightarrow [\text{"y4-C"}]))$
 $(y4\text{-C } ?x) \circ (\text{heap-update } (\text{PTR}(32 \text{ word}) \ \&(\text{'p} \rightarrow [\text{"y3-C"}])) (y3\text{-C } ?x) \circ$
 $(\text{heap-update } (\text{PTR}(32 \text{ word}) \ \&(\text{'p} \rightarrow [\text{"y2-C"}])) (y2\text{-C } ?x) \circ (\text{heap-update } (\text{PTR}(32 \text{ word}) \ \&(\text{'p} \rightarrow [\text{"y1-C"}])) (y1\text{-C } ?x) \circ \text{heap-update } (\text{PTR}(32 \text{ signed}$
 $\text{word}) \ \&(\text{'p} \rightarrow [\text{"x-C"}])) (x\text{-C } ?x))$

$c\text{-guard } ?p \implies \text{heap-update } ?p \ ?x = \text{heap-update } (\text{PTR}(32 \text{ word}) \ \&(\text{'p} \rightarrow [\text{"c2-C"}]))$
 $(c2\text{-C } ?x) \circ \text{heap-update } (\text{PTR}(32 \text{ word}) \ \&(\text{'p} \rightarrow [\text{"c1-C"}])) (c1\text{-C } ?x)$

$c\text{-guard } ?p \implies \text{heap-update } ?p \ ?x = \text{heap-update } (\text{PTR}(\text{closed-C}) \ \&(\text{'p} \rightarrow [\text{"fld4-C"}]))$
 $(fld4\text{-C } ?x) \circ (\text{heap-update } (\text{PTR}(32 \text{ word}) \ \&(\text{'p} \rightarrow [\text{"fld3-C"}])) (fld3\text{-C } ?x) \circ$

No restriction to *packed-type*!

In the original version of AutoCorres there was a restriction of heap lifting to types that are also in *packed-type*. Those are types that internally have no padding fields at all. The reason was that certain lemmas especially

regarding heap update become more involved in the presence of padding fields. A *heap-update* preserves the value of all padding bytes, whereas the abstract value obtained from a corresponding *h-val* is independent of the value of the padding bytes. So in principle these notions fit together well but it seems that some formal language was missing to reason about padding bytes. Meanwhile we added a theory to reason about those padding bytes in *AutoCorres2.Padding-Equivalence*. This made it possible to liberate heap lifting from the restriction to *packed-type*. For example $\text{heap-update } ?p \text{ ?arr} = (\lambda s. \text{foldl } (\lambda s n. \text{heap-update } (\text{array-ptr-index } ?p \text{ False } n) \text{ (?arr.[n]) } s) s [0..<CARD(?'b)])$ for *packed-type* holds in general $c\text{-guard } ?p \implies \text{heap-update } ?p \text{ ?arr } ?h = \text{fold } (\lambda i. \text{heap-update } (\text{array-ptr-index } ?p \text{ False } i) \text{ (?arr.[i])}) [0..<CARD(?'b)] \text{ ?h}$.

thm *heap-update-array*
thm *heap-update-Array*

Padding Equivalence and *xmem-type*

Padding bytes and padding fields are introduced via the construction of new C-Types via the combinators *ti-pad-combine* and *ti-typ-pad-combine* to satisfy alignment properties. However, the concept of a padding byte is not a first-class citizen of a $(\text{'a'}, \text{'b'})$ *typ-desc*, but just happens to be a field with some special properties. In practice these fields are generated by *ti-pad-combine*, so we know that the field name starts with *"!pad"*, and the associated 'lense' for lookup and update have the 'passthrough' properties of a padding field.

We made these properties explicit by supplying a theory to identify padding-bytes in a list of bytes associated with an C-Type, and having notions to compare such byte-lists, e.g. telling if two byte lists are equal up-to the padding bytes, or if they agree on the padding bytes. This information is also backed into the properties of *xmem-type*, which is a subclass of *mem-type*. All primitive word and pointer types as well as all types that are constructed by the UMM module of the C-Parser are proved to belong to that class. The construction of array types propagates the class as expected.

Again the notions come in pairs of a 'typed' and a 'untyped' version. The 'typed' version associated with *typ-info-t* is a lense based formalisation, the 'untyped' version associated with *typ-uinfo-t* is based on byte lists.

The lense based version is introduced by *padding-lense*. Access and update follow the approach of *'a field-desc*. Lookup / access has type $\text{'a} \Rightarrow \text{byte list} \Rightarrow \text{byte list}$. It takes an abstract value and a supply list of padding bytes and retrieves the bytes encoding the field. The intuition of the padding byte list is the following. It is supposed to bridge the gap between the abstract value and the byte representation. The abstract value is independent of the padding bytes. Hence in general there is no one-to-one correspondence between a byte list encoding of an abstract value and the abstract value.

When converting from a byte list to an abstract value this is fine, the padding bytes are just ignored. But when we go the other way we have to invent the padding bytes. One solution could be to just fill up with zeros. Another solution could be to yield a non-deterministic result for the padding bytes. The UMM model chose another way. The possible valuation for padding bytes is supplied as an additional argument. So whenever a padding byte is needed we just take it from the position in that list. The update has type *byte list* \Rightarrow 'a \Rightarrow 'a. It takes the value of a field, encoded as a byte list, and transforms it to an update on the abstract value.

context *padding-lense*
begin

The concept of a *padding-lense* follows the signature of 'a *field-desc* and describes the notions of padding bytes as semantic properties of the access function *acc* and the update function *upd*. Based on them it introduces the notions of

- *local.is-padding-byte*, is a byte a padding with respect to the lense?
- *local.is-value-byte*, is a byte a value byte with respect to the lense, i.e. does the abstract value associated with the byte list depend on that byte.
- *local.eq-padding*, access cannot distinguish the byte lists.
- *local.eq-upto-padding*, update cannot distinguish the byte list.

thm *is-padding-byte-def*
thm *is-value-byte-def*
thm *eq-padding-def*
thm *eq-upto-padding-def*

As the definitions are semantically defined the effect on *acc* and *upd* are rather immediate. For example, if two byte lists are equal upto padding, then an update with *upd* yields the same result. If the padding bytes within two supply byte lists are the same, then *acc v* yields the same result for both byte lists.

end

In the untyped *typ-uinfo-t* we define the corresponding notions, as properties of the byte list instead of the access and update functions.

- *is-padding-byte*, a byte is a padding byte in a byte list, if normalisation of the byte list is independent of its value. Normalisation *norm-tu* is defined on *typ-uinfo-t* and sets all padding bytes to zero.
- *is-value-byte*, normalisation depends on the value of the byte.

- *eq-padding*, all padding bytes are the same.
- *eq-upto-padding*, all value bytes are the same.

```

thm is-padding-byte-def
thm is-value-byte-def
thm eq-padding-def
thm eq-upto-padding-def

```

For instances of *xmem-type* we can go back and forth between both characterisations.

```

thm is-padding-byte-lense-conv
thm field-lookup-is-padding-byte-lense-conv
thm is-value-byte-lense-conv
thm field-lookup-is-value-byte-lense-conv
thm eq-padding-lense-conv
thm field-lookup-eq-padding-lense-conv
thm eq-upto-padding-lense-conv
thm field-lookup-eq-upto-padding-lense-conv

```

With those theorems in place it is easy to show that padding fields only consist of padding bytes and thus do not account to the abstract value.

```

thm field-lookup-qualified-padding-field-name(1)
thm is-padding-tag-def padding-tag-def padding-desc-def

```

UMM-Simprocs Cache

To solve sideconditions on UMM-Types we have implemented some simprocs within `UMM_Proofs`. Currently their scope is limited to the usecases we have in the proofs described above. It should be straightforward to extend them to more usecases. Their purpose is not to support abstract reasoning on types but to provide properties of concrete instances of C-types, for example deciding whether $TYPE(32\ word) \leq_{\tau} TYPE(outer-C)$ holds.

The benefit of the simprocs is that we do not have to guess and prove lots of lemmas already during the definition of a new UMM type, but can postpone it until we actually need them. Once they are proven they are added to the cache, so they are only proven once. In our use-case the lemmas we need depend on the addressable fields the user specifies on an `autocorres` invocation.

```

ML-val <
  val - = simproc <field-lookup>
  val - = simproc <type-calculations>
  val - = simproc <typuinfo-calculations>
  >

```

```

ML-val <
  Cached-Theory-Simproc.trace-cache @{context}
>

```

The simprocs make use of a common cache. The cache itself is implemented as a simpset. Cache lookup means we try to rewrite with the cache:

- cache miss: term is unchanged.
- cache hit: term is changed.

In case of a cache hit we are finished and return the resulting equation. In case of a cache miss we invoke the simplifier with a tailored simpset to derive a new equation. This equation is then added to the cache as well as returned from the simproc.

Some fine points of this setup are related to context management. Conceptually we only prove theory level theorems about an UMM type. So even if we prove them after the definition of the UMM type they should all be applicable as if we have immediately proven them at the point where the UMM type was generated. However, the simproc is invoked in some context later on where the theory has already advanced. In order to produce a result after a cache miss we have to somehow 'travel back in time' to the original theory context after the definition of the UMM type, such that the simplifier properly works on it and the result is reusable in other contexts. We maintain that original theory state and recertify terms before simplifying them.

Another point is, that the terms we attempt to simplify and cache might depend on each other. In order not to miss to cache intermediate results one has to carefully craft the simpsets.

In general the simplifier tries simprocs only after unconditional and conditional rules. So when a rewrite rule has already transformed the redex the simproc will never see that redex. This has two main implications:

- In order to have the simproc-based cache applied, there must not be a rule in the simpset that removes the redex before the cache actually has a chance to see it. This is why we maintain several simpsets to control that behaviour.
- When a cache miss was encountered and we apply the simplifier recursively to rewrite the redex we have to take care that the simproc is not invoked again on the same redex. When there is an unconditional rule in the simpset that rewrites that redex we are on the safe side. But beware of *conditional* rules. When the solver fails to solve the conditions the rule can fail and then the simproc is invoked again on

the same redex. To prevent the setup from looping in these cases we maintain the redexes the simproc has already seen.

Here are some principles in the design of the simprocs and their simpsets:

- The type descriptions obtained by *typ-info-t* are not fully expanded. Instead we use a simplifier setup that works on the combinators, like *empty-typ-info*, *final-pad*, *ti-typ-pad-combine*. This maintains the more compact representation of a type-descriptor as a combinator expression, which is anyways the way it is originally defined.
- Fieldnames for array indexes stay symbolic: *replicate i "1"*. We employ derived rules for array indexes and do not have to expand the type-descriptor of arrays. For these rules to apply we typically need the information that the index is in the bounds of the array type. In those cases the simproc generates a conditional rewrite rule.
- To test equality on *export-uinfo t = export-uinfo s* we normalise towards *export-uinfo (typ-info-t TYPE('a)) = export-uinfo (typ-info-t TYPE('b))*, where both 'a and 'b are concrete instances. Then when both expressions happen to be the same we have proved equality. Note that this approach is incomplete and in particular not sufficient to disprove the equality and prove the inequality. However, as these equality often appears as sidecondition in a conditional rewrite rule, not being able to prove the equality is somehow "equivalent" to disproving it: If we cannot prove the sidecondition the rule cannot be applied. The most prominent pattern for this is a *field-lookup* yielding the type-description of the selected field which is then compared to some type-description that is derived from a pointer type. To also disprove equality we make use of rule $(\text{export-uinfo } (typ\text{-info-t } TYPE(?'a)) = \text{export-uinfo } (typ\text{-info-t } TYPE(?'b))) = (TYPE(?'a) \leq_{\tau} TYPE(?'b) \wedge TYPE(?'b) \leq_{\tau} TYPE(?'a))$ and use the simproc on *sub-typ*.
- To decide whether e.g. $TYPE(32\ word) \leq_{\tau} TYPE(outer-C)$ holds or not, we first try to disprove it by using type name information $\llbracket typ\text{-name } (typ\text{-info-t } TYPE(?'a)) \neq pad\text{-typ-name}; typ\text{-name } (typ\text{-info-t } TYPE(?'a)) \notin td\text{-names } (typ\text{-info-t } TYPE(?'b)) \rrbracket \implies \neg TYPE(?'a) \leq_{\tau} TYPE(?'b)$. both *typ-name* and *td-names* are supplied by the UMM package: *typ-name (typ-info-t TYPE(data-struct2-C))* \equiv "data-struct2-C"
typ-name (typ-info-t TYPE(data-struct1-C)) \equiv "data-struct1-C"

26.21.7 Essence of Heap Lifting

Some birds eye view on what heap lifting is about. Consider the following C program.

```

typedef struct foo {
    int myint;
    bool mybool;
} foo;

int * p;
foo * q;

(*p) = 42;
i = q->myint;
b = q->mybool;

```

Is value *i* and *b* affected by update to **p*
 From the C-Parser we only get *c-guard p* and *c-guard q*:
 {*c_guard p* \<and> *c_guard q*}
 (*p) = 42;
 i = q->myint;
 b = q->mybool;

This only tells us something about alignment of pointers and that the pointer span does not overflow, but nothing about disjointness of the pointer spans.

What about stronger guarantees, if we assume well-typedness of the pointers:

```
{d \<Turnstile>\<^sub>t p \<and> d \<Turnstile>\<^sub>t p q}
(*p) = 42;
i = q->myint;
b = q->mybool;
```

Now we know that p might alias with $q->myint$ as they have the same type, but that pointer span p is actually disjoint from pointer span $q->mybool$. Hence for the read of b we can skip the heap update via p .

Now consider that the structure *foo* is a closed structure in the split heap model. This means that we have even stronger assumptions (which are guaranteed by guards in the lifted code):

```
{root_ptr_valid d p \<and> root_ptr_valid p q}
(*p) = 42;
i = q->myint;
b = q->mybool;
```

From this we can infer that the pointer spans p and the entire pointer span q don't overlap. hence reading i as well as b can skip the heap update via p .

In general the heap lifting phase introduces the potentially weaker guards for open types:

```
{ptr_valid d p \<and> ptr_valid p q}
(*p) = 42;
i = q->myint;
b = q->mybool;
```

So whether i might be affected by p depends on whether field *myint* is addressable or not.

The essential semantic part of heap lifting is to introduce these guards at every pointer access. In a second step these guards then allow a change in a representation from the monolithic heap to the split heap, with a separate heap for each atomic type. But in a sense this second step could be viewed as optional or cosmetic in the semantic sense. There is all the information available to perform the "skipping" steps as sketched above in the monolithic heap. This is what is performed in the simulation proof. So the question is if we could omit introduction of "lifted globals" completely and provide the necessary automation to the user to simplify accesses on the monolithic heap that mimic that behaviour in the split heap. In a sense instead of doing the simulation proof upfront it is done adhoc at every heap access / update. This avoids to provide quadratically many commutation lemmas (in the number of fields of open types) that are introduces for the lifted

globals.

From the perspective of the simulation proof alone such a "virtual" split heap, which does not introduce a new lifted-globals type, seems to be equivalent to the one which introduces a new type with concrete distinct record fields for each fundamental heap. The simulation proof only works when every pointer access is guarded and under that assumption the two representations behave the same.

However, besides the simulation there are other aspects of the split heap that might pay off for verification or further abstractions. The two models behave differently for invalid pointers: In the split-heap (with different record fields), updates to one heap still do not affect other heaps but we cannot properly model such updates in the monolithic heap at all.

Another aspect was introduced later on for stack allocation: non-deterministic padding bytes. The *typ-heap-simulation* was generalised to state that lifting to the split heap is invariant for arbitrary padding bytes, i.e. *write-simulation*. The lifted heap only cares about the abstract values were the values of the padding bytes become irrelevant.

27.1 Local Variables

Local variables in the SIMPL outcome of the C-Parser are represented in *locals*. The natural number in the domain encodes the canonical position in the scope of the C-function: input arguments, then return variable, then local variables. The byte list in the range of the function is the encoding of the value according to the UMM (unified memory model) *c-type*. The typing of variables is maintained as data in `CLocals` and a typed view is achieved via *lookup* and *cupdate*.

In previous attempts local variables were represented first as a **record** and more recently as **statespace**. The representation as *locals* tries to combine the best of all previous approaches:

- Uniform (program independent) representation of local variables.
- Positional 'naming' enables a canonical parameter passing for function calls, even if the names of parameters are unknown, as in the case of function-pointers.
- Lightweight "typing" via ML infrastructure instead of the 'fixes' of **statespace**. Unfortunately, the more flexible **statespace** representation for local variables turned out to reveal some performance bottleneck in the locale infrastructure, which itself boils down to the resources consumed by the omnipresent instantiation of types and terms.

```
declare [[ML-print-depth = 1000]]
```

27.1.1 Basic ML primitives

To define new variables the basic primitive is `CLocals.define_locals` which takes a scope (currently a two element list of qualifiers: program-name followed by function-name) and the list of local variable declarations (name, type and kind). Note that the order is relevant as it represents the canonical positional ordering.

```
setup <CLocals.define-locals [prog, myfun] [  
  (x, @{typ <32 word>}, NameGeneration.Loc),  
  (p, @{typ <32 word ptr>}, NameGeneration.Loc),  
  (z, @{typ <64 word>}, NameGeneration.Loc)] >
```

```
ML <CLocals.Data.get (Context.Proof @{context})>
```

For each local variable a constant is defined with the position of the variable. The constant name encodes the original name of the local variable. Whenever available we use this symbolic name in favour of the plain literal number. However, at some places we use the plain numbers, in particular for parameter passing. There is some simplifier setup which we explain later that allows to use either representation.

To enable syntax translations from short names to the symbolic constants together with their typing one has to enter the correct scope, e.g.:

```
local-setup <  
Local-Theory.declaration {pervasive=false, syntax=true, pos = here} (fn - =>  
  CLocals.scope-map (K [prog, myfun]))  
>
```

```
term prog.myfun.p-'  
thm prog.myfun.p'-def
```

Some remarks on the naming scheme for those symbolic constants. The qualifiers for both program-name and function-name are mandatory. The name mangling with the suffix serves two purposes:

- Avoid name clashes with user input via variable names in the C sources (in particular for the artificial return variable)
- Avoid name clashes for bound or free variables (or new constants) in HOL. Note that even a constant with mandatory qualifier e.g. `foo.c` would force the pretty printer to avoid a bound variable being named just as `c`. The pretty printer only takes the `Long_Name.base_name` into account.

The general suffix `-'` avoids clashes with C variable names as the prime is not a legal character for C identifiers. Syntax translations will truncate this suffix. The artificial return variable `ret` that the C-Parser introduces is internally `ret'-'` to avoid a potential conflict with a local variable named `ret`.

ML $\langle CLocals.Data.get (Context.Proof @\{context\}) \rangle$

27.1.2 Syntax

Plain lookup and update in locals.

term $\langle l \cdot p \rangle$

ML-val $\langle term \langle l \cdot p \rangle \rangle$

term $\langle s \langle x := y \rangle \rangle$

term $\langle s \langle x := y, p := k \rangle \rangle$

ML-val $\langle term \langle s \langle x := y \rangle \rangle \rangle$

ML-val $\langle term \langle s \langle x := y, p := k \rangle \rangle \rangle$

Lookup and update in a complete Simpl state, selecting the *locals*

term $\langle s \cdot_{\mathcal{L}} p \rangle$

ML-val $\langle @\{term \langle s \cdot_{\mathcal{L}} p \rangle \} \rangle$

term $\langle s \langle x :=_{\mathcal{L}} y \rangle \rangle$

term $\langle s \langle x :=_{\mathcal{L}} y, p :=_{\mathcal{L}} k \rangle \rangle$

27.1.3 Simplifier setup

The simplifier is setup to be able to deal with symbolic as well as literal numerals. Symbolic ones are expanded on the fly employing the infrastructure from the code generator. The trigger for this expansion is via a simplification procedure that. Conditional rules can be configured via the attribute:

ML $\langle @\{attributes [code-simproc]\} \rangle$

The simplification procedure first checks wheter the precondition evaluates to true, via the code-generator. In case of success the simplifier is invoked to replay that proof and trigger the rule. `Code_Simproc.code_simp_prem`s, `Code_Simproc.code_prove`.

Note that the attribute also consumes an optional name to index the simprocs. This name is taken from **named-theorems**.

The relevant setup of the rules can be found in `CLocals.thy`.

schematic-goal $\langle (lookup\ 2\ (cupdate\ prog.myfun.z^{-1}\ (\lambda-. 2::64\ word)\ l)) = (?X::64\ word) \rangle$

apply *simp*

done

schematic-goal $\langle (lookup\ prog.myfun.z^{-1}\ (cupdate\ prog.myfun.z^{-1}\ (\lambda-. 2::64\ word)\ l)) = (?X::64\ word) \rangle$

apply *simp*

done

schematic-goal $s \langle x := \lambda-. 2 \rangle \cdot x = ?X$

```
apply simp
done
```

```
schematic-goal  $s\langle x := \lambda-. \varrho \rangle \cdot p = ?X$ 
apply simp
done
```

```
install-C-file ex.c
```

```
thm size-td-simps
```

The root locale storing the global content *ex-global-addresses*. This is also the locale where the bodies of the imported functions are defined.

```
context ex-global-addresses
begin
```

The usage of global variables is analysed and three cases are distinguished:

- static variables do not change their value. So they are defined as HOL constant with their initial value. In case no initialiser is given they are zero initialised.
- 'ordinary' global variables that are also updated somewhere in the code are stored in the record of global variables *globals*. They are accessed by the lookup and update function of the **record** package.
- In case the address of a global variable is taken somewhere in the code, we declare a global constant for a pointer to that variable. Lookup and update is then indirectly via the heap. Note that the pointer is only declared. There is no defining equation. Currently there are also no assumptions maintained about distinctness of global variable pointers. This is up to the user.

```
thm global-const-defs
term g-static
term g-ordinary-' term g-ordinary-'-update
term g-addressed-'
thm main-body-def
thm globals.typing.get-upd
thm state.typing.get-upd
```

Functions also result in a declaration of a constant representing the global function pointer. *ex.add*. They have the type *unit ptr*.

```
term ex.add
```

When the code actually uses function pointers to perform indirect calls, some more infrastructure is provided, cf `../doc/fnptr.thy`

When looking into the function bodies the symbolic names for the positional local variables are displayed, fully qualified with program name as well as function name.

```
thm add-body-def
```

To have short names printed, one can either enter the scope of the function by activating the corresponding *variables* bundle, or use the option to always display short names.

```
context includes add-variables
begin
thm add-body-def
end
```

```
declare [[locals-short-names]]
thm add-body-def
end
```

The canonical locale to do verification of a procedure is the *impl* locale. This activates the scope of the function and also stores the equation that the lookup of the function pointer in the environment Γ retrieves the expected body.

```
context add-impl
begin
thm add-body-def
thm add-impl
```

The symbolic names can be folded and unfolded by an attribute.

```
thm add-body-def [unfold-locals]
thm add-body-def [unfold-locals, fold-locals]
```

These attributes can also take qualifier in case an alternative scope should be added

```
thm call-add-body-def
thm call-add-body-def [unfold-locals] — nothing happens as we are in the wrong scope
thm call-add-body-def [unfold-locals call-add] — now they are expanded as we qualify the scope

end
```

```
context call-add-impl
begin
thm call-add-body-def
declare [[hoare-use-call-tr' = false]]
thm call-add-body-def
end
```

All the implementations of the program are gathered in the *simpl* locale

```

context ex-simpl
begin
thm add-impl
thm call-add-impl
end

```

27.2 Infrastructure for states

```

type-synonym state = (globals, locals, 32 signed word) CProof.state

```

```

context add-impl
begin

```

As a final part of the verification generator generator terms containing local and global variables are generalised to a 'splitted' view, where each component becomes has a bound variable.

```

Chapter 28

Translation of the **StrictC** Dialect (Outdated)

MICHAEL NORRISH

28.1 Introduction

This report describes the translation program that imports C source into a running Isabelle/HOL process, making a series of Isabelle definitions in the process, as well as discharging a number of (relatively minor) proof obligations that arise along the way.

The source code for the translator is found in the directory `c-parser`. Source files, *e.g.*, `file.ML`, are found in this directory unless otherwise noted.

The translation expects its input to be a well-formed C source file. Such a source file must additionally satisfy a number of other constraints, giving rise to a subset of C that is here called “**StrictC**”. Files in **StrictC** may also include special annotations intended only for consumption by Isabelle (and the human code-verifier).

In fact, there are two important **StrictC** programs: the translation program, and the analysis program. The analysis program is entirely independent of Isabelle, and can be used to check that a source file conforms to the **StrictC** subset. It also implements a number of analyses that can be performed on source code. For example, it can output the input file’s call-graph, and can list the globals that are read or modified in each function. The additional source-files supporting the analysis program are found in

`c-parser/standalone-parser`

The rest of this report describes both the functionality provided by these programs (focussing on the translator), how this functionality is implemented, and *where* it is implemented. The aim is to give a picture of the systems’ design in a way that should make future modification of the code possible.

28.1.1 StrictC Subset Summary

This is a brief list summarising the simplest restrictions imposed by the StrictC subset.

- No `goto` statements.
- No fall-through cases in `switch` statements. Cases can be terminated with `continue` and `return`, as well as `break`.
- Labels for `switch` statement cases must all appear at the syntactic level immediately below the block statement that must appear below the `switch` statement.
- No unions. (These are handled by a separate tool; see Cock [1].)
- No `struct`, `enum` or `typedef` declarations anywhere except at the top, global, level.

28.2 Abstract Syntax

The core data types in the translator represent the input program. These abstract syntax values are the product of parsing the concrete syntax (see Appendix 28.6 for the grammar used), and is the subsequent input to all further analyses and translation. The abstract syntax declarations are given in `Absyn.ML`. For example, the definition of the syntax type corresponding to C statements is given in Figure 28.1. There are also definitions for C types, expressions, and declarations in `Absyn.ML`.

The type `statement` is actually a `statement_node` wrapped inside a “region” (see `Region.ML` and Section 28.2.1 below), which provides information about where the original concrete syntax originated. This is used for providing error messages.

All strings in the statement declaration correspond to Isabelle terms (*e.g.*, the loop invariant in the `While` case). These will be parsed as such later in the translation process, but are just uninterpreted strings when the C parser finishes. Function calls can return their results into l-values, have the return value ignored, or have the return value itself `return`-ed. The first option corresponds to having the `expr_option` argument be `SOME e` in the `AssignFnCall` constructor, the second would have that parameter be `NONE`, and the last is handled by the `ReturnFnCall` constructor.

Syntactically, these options correspond to writing

```
var = f(x,y);
```

or

```
f(x,y);
```

```

datatype statement_node =
  Assign of expr * expr
  | AssignFnCall of expr option * expr * expr list
  | EmbFnCall of expr * expr * expr list
  | Block of block_item list
  | While of expr * string wrap option * statement
  | Trap of trappable * statement
  | Return of expr option
  | ReturnFnCall of expr * expr list
  | Break
  | Continue
  | IfStmt of expr * statement * statement
  | Switch of expr * (expr option list * block_item list) list
  | EmptyStmt
  | Auxupd of string
  | Spec of ((string * string) * statement list * string)
  | AsmStmt of {volatile : bool, asmblock : asmblock}
and statement = Stmt of statement_node Region.Wrap.t
and block_item =
  BI_Stmt of statement
  | BI_Decl of declaration wrap

```

Figure 28.1: The Abstract Syntax Data Type for C Statements

or

```
return f(x,y);
```

C99 Block Items Conforming to the C99 grammar, the input language allows declarations at any point inside a block, not just in a sequence at the head of the block. In other words, the following

```
{
  x = f(z);
  int y = x + 1;
  while (x < y) { ... }
}
```

is legal in C99. This means that a block has to take a list of `block_item` values as an argument, where a `block_item` is either a statement or a declaration.

Syntactic Sugar for Loops The abstract syntax has just one form of loop, the `While` constructor. The optional string argument to `While` is used to represent any user-supplied invariant. Together with the `Trap` constructor, this is used to implement all three forms of C loop. The translation follows the model from Norrish's PhD [6, p60]. It also supports `for`-loops with declarations in the first position. This latter, for example,

```
for (int i = 3; i < 10; i++) ...
```

is a feature of C99.

Breaking from C, the grammar has the third component of the `for` loop form be a restricted form of statement, rather than an expression. The parser syntax only allows comma-separated increments (*i.e.*, `++`), decrements and assignments.

The Isabelle translation eventually compiles all loops to one underlying the loop primitive in the VCG environment called `While`. This form does not handle exceptional control-flow forms like `break` and `continue`. These are instead handled by the `Trap` constructor, mapping to the VCG language's `TRY-CATCH` form.

28.2.1 Regions

The `Region` module implements a method for annotating arbitrary data types with location information. This module has been taken from the `MLton` compiler project (which has a BSD-style open source licence). It is used a great deal in the system, and its use could probably be extended still further. Region information is used to produce good error messages.

The basic type is that of the `region` which is essentially a pair of “source positions” (which are in turn implemented in `SourcePos.ML`). One useful source position is `SourcePos.bogus`, corresponding to “nowhere” (perhaps because some syntax has been conjured out of nowhere and doesn’t really exist in a file).

Regions are then used to implement the concept of a “wrap” (SML type `Region.Wrap.t`), a polymorphic data type. The file `Absyn.ML` declares the following abbreviation:

```
type 'a wrap = 'a Region.Wrap.t
```

An `'a wrap` (read “alpha wrap”) is an `'a` value coupled with a region. The important functions for manipulating wraps are

```
val wrap      : 'a * SourcePos.t * SourcePos.t -> 'a wrap
val bogwrap  : 'a -> 'a wrap
val left     : 'a wrap -> SourcePos.t
val right    : 'a wrap -> SourcePos.t
val node     : 'a wrap -> 'a
val apnode   : ('a -> 'b) -> 'a wrap -> 'b wrap
```

For example, the grammar code in `StrictC.grm` manipulates a number of values of type `string wrap`. If an error relating to this value arises, both the string and its position can be reported to the user.

Things become more complicated when the type to be wrapped is recursive. The standard idiom in the project is illustrated with the definition of the `statement` data type (shown in Figure 28.1). The constructors for values of the type are actually given in an auxiliary type (`statement_node`), but the recursive constructors take arguments of type `statement`. The type `statement` is then a type that is mutually recursive with `statement_node`, and which has just one constructor, `Stmt`.¹

Because a `statement` is not a wrap, the project cannot directly call functions like `node` on `statement` values. Instead, helper functions are declared:

```
val sleft   : statement -> SourcePos.t
val sright  : statement -> SourcePos.t
val snode   : statement -> statement_node
val swrap   : SourcePos.t * SourcePos.t * statement_node ->
              statement
```

When code wishes to pattern-match against the multiple possible forms a `statement s` may have, the idiom is to write

¹It would be nice if one could just declare `statement` to be an abbreviation of `statement_node wrap`, but SML doesn’t permit this. It must be a `datatype` itself, and thus must have at least one constructor.

```

case snode s of
  EmptyStmt => ...
| While(g,inv,body) => ...
| IfStmt(g,ts,es) => ...
| ...

```

The strength of this idiom is that one *always* manipulates values of type `statement`. In particular, if the case analysis above is to make recursive calls of its analysis on sub-statements such as `body`, `ts` and `es`, these values are of the correct type for this to be done immediately.

The `expr` (expression) type (home to constructors such as `Deref`, `Var` and `TypeCast`) is set up in the same style, giving rise to functions `elleft`, `eright`, `enode`, `ewrap` and `ebogwrap`.

The type of C types The type of C types is `'a ctype`, with constructors such as `Void` and `Ptr`. Though recursive, it doesn't use the wrap idiom. On the other hand, this type is polymorphic. The `'a` parameter is instantiated with an SML type that corresponds to the forms that give the size of arrays when they are declared. This type parameter is instantiated with `expr` when the input file is first parsed. In this way, a declaration like

```

unsigned char array[EnumConst1 * sizeof(int*)];

```

can be handled. Thus, the `VarDecl` constructor of the declaration type

```

val VarDecl :
  expr ctype * string wrap * bool * initializer option ->
  declaration

```

takes an `expr ctype` as its first parameter. Within subsequent phases of the analysis and translation, it is much more convenient to work with values of type `int ctype`, where the (constant) expression has been evaluated. For example, the `get_reftype` function from `program_analysis.ML`, takes a `csenv` value (see Section 28.3 below) and the name of a function, and returns the return type of the function. The value returned is an `int ctype`. The conversion of an `expr ctype` into an `int ctype` is done by the function `Absyn.constify_abtype`.

28.3 The Symbol Table

All of the work done in analysis and translation of `StrictC` revolves around the information stored in two important data structures implemented in the module `program-analysis.ML`. The first of these is the `var_info` type. This stores information about individual variables. The second type, `csenv` ("C state environment"), stores information about the program as a whole,

including its collection of variables, but also recording details such as where variables are read and modified, and the program's call-graph structure.

The `var_info` type stores information about declared identifiers living in the name-space that encompasses normal objects, functions and enumeration constants. In addition to the type of the variable (*e.g.*, `int`, `char *` *etc.*), the `var_info` also includes information about where the variable was declared in terms of program locations, and also in terms of scope (it might be global, or declared local to a particular function).

The `csenv` type accumulates its information about the program by performing traversals of the abstract syntax tree. **The StrictC translator makes no effort to be a one-pass compiler**, but the number of traversals is no greater than three, and will probably be reduced in future versions of the implementation. These traversals are performed after the parser has constructed all of the tree. There are also places in this analysis where **the translator assumes that it has seen the whole program**. In particular, the translator cannot be used to translate *translation units* that are to be separately compiled. It must be presented with a concatenation of the complete sources.

The bulk of the API for manipulating values of type `csenv` is concerned with pulling information out of the symbol table. For example, it is possible to calculate the type of a C expression with the function

```
val cse_typing : csenv -> expr -> int ctype
```

In addition, `program-analysis.ML` contains the one entry-point for taking a sequence of external declarations (once parsed) and creating a `csenv` value:

```
val process_decls :  
  Absyn.ext_decl list ->  
  ((Absyn.ext_decl list * Absyn.statement list) * csenv)
```

The return type includes a modified version of the syntax that was provided as input, a list of the initialising assignments for the global variables, and the `csenv` value.

28.3.1 Functional Record Updates in SML

The code in `program-analysis.ML` uses a powerful, but cryptic SML idiom that makes it easy to define SML records along with functions for updating their fields. Done naïvely, writing code to do this represents a quadratic amount of work for the programmer. Put another way, the naïve approach requires $O(n)$ much typing whenever a field is added to or removed from a record definition of n fields.

The cryptic technique is fully described at

<http://mlton.org/FunctionalRecordUpdate>

and allows the addition or deletion of a field to be done with $O(1)$ much typing. Supporting code is in `FunctionalRecordUpdate.ML`.

The cryptic code is isolated within `program-analysis.ML`, where it is used to define update functions that are subsequently used exclusively. In general, when one of the two types has a field `fld` of type τ , then there will typically be a function `{cse|vi}_fupd_fld` defined, with type

$$(\tau \rightarrow \tau) \rightarrow \text{rcd} \rightarrow \text{rcd}$$

where `rcd` is either `var_info` or `csenv`. Such functions can be used to update the fields of a record: the user provides a function that is given the old value of the field, and which returns the new value.

28.4 Creation of the Hoare Environment State

The major oddity about Norbert Schirmer’s Hoare environment, into which we are translating our programs, is that all local variables, including function parameters, have to be part of the “global state”. This state must be declared before any functions can be translated, because a function becomes an Isabelle definition (conceptually at least) that operates over that state space.

Slightly simplifying, the state space is an Isabelle type that is a record with fields for every local and global variable. Each field has a type (Isabelle/HOL is a typed logic after all), which means that all local variables of the same name in the same `StrictC` translation unit must have the same type. This is rather an arbitrary requirement, but easy both to enforce and to comply with. Thankfully, signed and unsigned variants of the same underlying type (such as `signed short` and `unsigned short`) are given the same Isabelle/HOL type, so there is a little leeway. Nonetheless, if `i` is of type `int` in one function, it can not be of type `char` in another.²

The arrangement of global and local variables is actually slightly complicated. In essence, the state-space is set up to look like:

```
statespace = record
  globals :: global_var_type
  local_var1 :: lvar1_type
  local_var2 :: lvar2_type
  ...
  local_varn :: lvarn_type
```

²If this is attempted, the system will “munge” one of the variables so that it has a different name when translated into Isabelle. The “munged” name is stored in the variable’s `var_info` record.

where the field `globals` is of a custom record type `global_var_type` that in turn contains all of the global variables. In addition to the user program’s own globals, the translation process adds two extra global variables of its own. These variables are used for handling “exceptional exits” (such as those caused by the `break`, `continue` and `return` statements), and for modelling the global heap. The exact names of these variables is not important, here we will refer to them as `global_exn_var`, and `global_heap`.

These two special variables are part of `global_var_type` and so must have Isabelle types themselves. The type of `global_exn_var` is the enumerated type `c_exntype`, defined in the Isabelle theory `CProof` to have three possible values, `Break`, `Return` and `Continue`. The type of the global heap `global_heap` field is a product of underlying heap contents (a map of type `addr → word8`) and a special-purpose data type to store type information about the heap memory (see Harvey Tuch’s PhD thesis [9] for more on this).

28.4.1 Representing Values in Memory

There is one important requirement that must be met by all object types that occur in C programs: they must be representable in memory. Alternatively, it must be possible to encode values of the types in a program as sequences of bytes, and to then decode those same bytes back into the original values. One approach to modelling this fundamental requirement might be to have Isabelle functions that manipulated only lists of bytes. Working at the level of this untyped, and very concrete, view of the program state would be an extremely poor state of affairs (the C programmer would have a more abstract view of the program than the verifier).

Our approach is to use Isabelle type-classes to encode the fact that an Isabelle type can be represented in a consistent amount of “C memory”. When an Isabelle type `'a` is in the class `mem_type`³, it supports functions

```
to_bytes   :: "'a::mem_type => byte list"
from_bytes :: "byte list => 'a::mem_type"
```

as well as a number of other supporting functions that record details like the fields that occur in compound `struct` types, and the (constant) length of the byte-lists that encode the values in the type.

All of the atomic types manipulated by our programs are fixed-width words (*e.g.*, 32 bit words for integers). It is easy to demonstrate that these types are indeed in the `mem_type` class. In particular, we do *not* pretend that programs manipulate infinite precision integers, and then worry about whether or not these integers can be pushed into and pulled out of memory. All of the arithmetic performed by the programs we verify is done at fixed widths, respecting the underlying machine’s operations. Additionally, using

³See `umm_heap/CTypes.thy`.

the techniques from Section 28.5.1, we trap the undefined behaviour caused by overflow on signed values.

28.4.2 Pointers

Pointers are always represented as words of a particular size (regardless of type being pointed to). This is not required by the C standard, which only requires pointers to `void` be capable of storing all other non-function pointer values, and that all function pointer values be inter-convertible. Again, our decision to specialise on particular, and reasonable, target architectures makes life simpler.

Pointers retain type information by using “phantom” type variables. The Isabelle declaration is

```
datatype 'a ptr = Ptr addr
```

Then, if the C program under analysis calls for a variable of type `char *`, the Isabelle environment will include a variable of Isabelle type `byte ptr`. In this way our pointers are typed, even if their underlying encoding makes it trivial to view a pointer to one type as a pointer to another type.

Because the underlying representation is always the same, all pointer types are proved to be in the class `mem_type` once and for all (in theory `CTypes`). Pointers to `void` are represented as values in the Isabelle type `unit Ptr`, where `unit` is the standard singleton type. The `unit` type is not shown to be in the class `mem_type`.

28.4.3 Arrays

C arrays are lists of values of fixed length. A faithful representation of this type requires a novel Isabelle type. We build on Anthony Fox’s implementation of John Harrison’s “finite Cartesian products” idea [4]. Syntactic trickery within Isabelle allows us to write types like

```
nat[10]
```

which is an array of 10 natural numbers. There are operators for updating and indexing into arrays. Note that the type `10` that appears above is an Isabelle *type*, not a term.

If type τ is a `mem_type`, then an array of τ values will also be a `mem_type`, as long as the size of the array is not so large that the array would not fit into memory. This condition is discharged as the `StrictC` program is translated.

For technical reasons due to the implementation of type classes in Isabelle, we need to fix separate limits, ahead of time, on the number of elements in an array and the size of each element. Currently, for 32-bit ARM, our model fixes a maximum of:

```

struct listnode {
    int node_data;
    struct listnode *next;
};

struct node2;
struct node1 {
    struct node2 *data;
    struct node1 *next, *prev;
    int someflag;
};
struct node2 {
    struct node1 *owner;
    char stringdata[100];
};

```

Figure 28.2: Examples of Recursive `struct` Declarations Accepted in StrictC

- 2^{13} (8192) elements in each array; and
- 2^{19} bytes (512 KiB) in each array element

For x86-64, the limits are:

- 2^{20} (1048576) elements in each array; and
- 2^{26} bytes (64 MiB) in each array element

One would prefer to be able to multiply the size of the element type by the number of the elements, but the type system does not permit this (for good technical reasons).

28.4.4 C `struct` Types

From the point of view of the translation into Isabelle, `struct` types do not pose any great conceptual difficulties. A `struct` type is clearly very similar to an Isabelle record, which in turn is conceptually the same as a tuple. The first complication that arises is that Isabelle tuples can not be recursive, whereas C `struct` types are often recursive (as when implementing linked structures in the heap).

This required the implementation of an alternative record definition package, allowing (possibly multiple) recursive types. This then allows Isabelle types to be defined that correspond to C declarations such as those shown in Figure 28.2.

Confirming that a `struct` type really is representable in memory, requires the definition of functions for converting Isabelle records into lists of bytes and *vice versa*. The size of the converted value must also be checked to be no bigger than the size of memory. Both of these actions require knowledge of how the fields of the `struct` are laid out in memory, which is in turn a function of the padding that can be inserted between the fields. Such calculations are architecture dependent.

28.5 Translating Expressions

Expression translation is implemented in `expression_translation.ML`.

Fundamental Concepts StrictC expressions are essentially a subset of C expressions, and are fairly easy to translate to corresponding Isabelle expressions that manipulate Isabelle-encoded values. There are two fundamental concepts to grasp of expression translation. First, when being evaluated (“read to determine a value”) a C expression of type τ becomes an Isabelle expression of type `statespace` \rightarrow $\llbracket\tau\rrbracket$, where $\llbracket\tau\rrbracket$ is the translated, Isabelle version of C type τ .

This must be done to make sense of expressions that read memory: an expression such as `s.arrayfld[3]` only has a specific value in the context of a specific state of memory. This use of a “lifted” function space to represent the expression is a standard technique in denotational semantics. In the example given, the value of the expression is a function that looks at the statespace to determine what data is stored at variable `s`. As the statespace evolves, the value returned from this function changes, but the function’s value is the same.

Expressions do not just determine values however, they can also denote an *l-value*, something denoting a “place in memory” that is to be updated. This is done when an address is taken, or when an assignment is to be performed. In a simple language, l-values might only be variable names, but C allows for complicated expressions on both sides of an assignment. The example above (`s.arrayfld[3]`) might just as well be assigned to as read. So, the l-value of an expression e that has type τ will be an Isabelle value of type `statespace` \rightarrow τ \rightarrow `statespace`, a function that takes a new value and a statespace to change, and returns the updated statespace.

Not all expressions are l-values (the expression `3` is not, for example), so the translation of any one expression can return one or two different values, an “r-value” as well as an optional l-value.

In addition, because of the way the translation does not put local variables into memory, the translation provides another separate optional value, that of the expression’s address. If everything did live in memory, all l-values would have addresses, and one could dispense with the separate calculation of l-values. Thus the first three lines of Figure 28.3.

The SML types given to the `lval`, `addr` and `rval` fields in the declaration of `expr_info` are themselves function spaces at the SML level. These function spaces manipulate values of SML type `term`. The way in which typing at the C level is reflected at the Isabelle level is mainly hidden at the SML level, where the programmer just manipulates terms (the Isabelle types are internal to those values).

However, the function spaces *can* be made visible at the SML level. This is done mainly to reduce the number of β -redexes that would otherwise be

```

datatype expr_info =
  EI of {lval   : (term -> term -> term) option,
        addr   : (term -> term) option,
        rval   : term -> term,
        cty    : int ctype,
        ibool   : bool,
        lguard : (term -> term * term) list,
        guard  : (term -> term * term) list,
        left   : SourcePos.t,
        right  : SourcePos.t }

```

Figure 28.3: The `expr_info` type, into which C expressions are translated internally.

created in the resulting term. For example, translating the C expression `x + 3` will first create r-values

$$\begin{aligned} \llbracket x \rrbracket &= (\lambda\sigma. x(\sigma)) \\ \llbracket 3 \rrbracket &= (\lambda\sigma. 3) \end{aligned}$$

where the application of the `x` function to a statespace σ pulls out the value of variable `x` in σ .

When translating an expression $e_1 + e_2$, one naturally creates the value

$$\lambda\sigma. \llbracket e_1 \rrbracket(\sigma) + \llbracket e_2 \rrbracket(\sigma)$$

If this was done within Isabelle `term` values, the result would be a `term` full of expressions of the form $(\lambda v. M)N$. By lifting the Isabelle λ to the SML level, only one abstraction need to be created, at the very top-level in the translation. Thus, the translation of the addition becomes the SML expression

```
(fn s => mk_plus (rval_of e1 s) (rval_of e2 s))
```

where `rval_of` returns the `rval` field of an `expr_info` and the β -reduction happens within SML.

The fourth line of the record in `expr_info` values stores the type of the expression, something that informs the translation of many different C expressions. For example, additions are not as simple as just presented because of the possibility that one of the arguments might be a pointer. The `left` and `right` fields of the `expr_info` record store the source-code position of the original expression. The two guard fields are explained below in Section 28.5.1.

The `ibool` field of the `expr_info` records whether or not the term being generated in the r-value is of Isabelle's boolean type. This is done so that

translation can avoid some conversions between Isabelle words and booleans. For example, if the expression being translated is `x < 6 && y > 10`, the resulting Isabelle term will include a use of the two comparison operators on words. Strictly, one should then turn the boolean results of these operators into either a one or zero. But, as these results are then combined with boolean conjunction, the values will immediately be converted back into booleans.

Of course, in an expression such as `x && x->fld > 6`, the first operand to the conjunction does not have Isabelle boolean type, and will be converted to a boolean value by comparing it with the null pointer. (In fact, this particular example causes a more complicated translation effect to occur; see Section 28.5.1 below on undefined behaviour.) Dually, if the code puts a boolean value into memory, the translation has to make sure that the Isabelle term has the appropriate word type once more. There are two functions used here:

```
mk_isabool : expr_info -> expr_info
strip_kb   : expr_info -> expr_info
```

The function `mk_isabool` produces an `expr_info` value that does have Isabelle boolean type (it will be the identity function on an r-value that is already known to be boolean). The function `strip_kb` reverses this, turning an Isabelle boolean into an Isabelle word if necessary.

28.5.1 Undefined Behaviour

There are three classes of under-specification in the C standard. Those classed as *implementation defined* are behaviours or values that are supposed to be fixed and documented by particular implementations. For example, the number of bits in an `int` (a number that must be at least 16), is a fixed value that implementations are allowed to choose themselves. Because `StrictC` targets a particular architecture, most implementation-defined aspects of C can be “baked into” the translation. (The design attempts to have the translation sources be easy to modify to account for different architectures; see for example the `ImplementationNumbers` structure in each of the `TargetNumbers.ML` files.)

The second class of under-specification comprises *unspecified* behaviours. The most important of these is the order of evaluation of arguments to operators and function calls. Therefore, one should avoid writing code that depends on unspecified evaluation order. Otherwise, the compiled executable might have different semantics compared to the `Simpl` specification that we generate. For example:

```
int x = f() + g();
```

where `f` and `g` both have side effects, is currently allowed but should be avoided. In the future, we plan to forbid or restrict programs that may have unspecified evaluation order. The standalone analysis tool can check for this problem using the `-embedded_fncalls` option.

The third class of under-specification is *undefined behaviour*. In essence, undefined behaviours are runtime errors (such as dereferencing a null pointer). They are undefined because the standard does not require the implementation to catch them, or to realise that they have occurred. Rather, if an undefined behaviour occurs, the user can no longer rely on their program to do anything sensible. In effect, implementations are given licence to blunder on however they like when an undefined behaviour occurs.

Thus, it is critical that the C code we verify never exhibits any undefined behaviours. We do this with a feature of the Hoare environment called the *guard*. A guard is a boolean condition g attached to a statement s , with the combination written $g \rightarrow s$. If the guard g is true when the combined statement is to be executed, then s is allowed to execute. If it is false, the underlying semantics defines the result to be a “fault”. When a program faults, nothing more can happen, so it has effectively aborted. Verifying a program with guarded statements thus requires proofs that the guards are always true.

Most guards arise in expressions, and the translation process accumulates these in one top-level guard at the statement level. For example, in the statement

```
x = *p >> i;
```

there will be four guards attached to the statement that will need to be discharged: that `p` is not null, that `*p` is not negative, that `i` is not negative, and that `i` is less than 32.

One elegant feature of guards in the Hoare environment is that they can be selectively disabled for the purposes of verification. For example, the C standard’s requirement that right shift operations might not be performed on negative numbers (that it results in undefined behaviour) is too strict, given a particular C compiler and target architecture. In this situation, it is possible to prove Hoare-triples where that particular guard is not used, so that the semantics of $g \rightarrow s$ is simply that of s .

28.6 Concrete Syntax: Parsing and Lexing

The grammar for `StrictC` is given in the file `StrictC.grm`, which is given as input to the standard tool `mlyacc`. The format of an `mlyacc` file looks quite similar to the format accepted by `yacc`. A typical grammar rule is

```
init_declarator_list
: init_declarator
```

```

        ([init_declarator])
    | init_declarator YCOMMA init_declarator_list
        (init_declarator :: init_declarator_list)

```

where a non-terminal appears before a colon, and multiple possible right-hand sides are separated by the pipe or vertical bar character. The code for a production appears in parentheses after each right-hand-side. The code's convention is to have token names (*e.g.*, YCOMMA above) be upper-case.

Apart from the changes that turn assignment expressions into statements, the grammar for `StrictC` attempts to be as close as possible to the grammar of the C standard. In general, the names for non-terminals in `StrictC.grm` are taken from the standard, so it should be fairly clear how the standard's grammar has been mapped into `StrictC.grm`.

28.6.1 Lexing and typedef Names

The standard problem in lexing and parsing C is that the grammar is ambiguous: the non-terminal *typedef-name* is defined to simply be the same as an *identifier*. When the parser encounters

```
x * f(y);
```

it can't know if this is meant to be a multiplication of variable `x` by a function call expression, or whether it is the (prototype) declaration of a function called `f` taking an argument of type `y` and returning a value of type `x`.

To resolve this, the lexer must be able to classify identifier tokens as normal identifiers or *typedef-names*. The `StrictC` translator's approach to this problem is not typical, because of the strange way in which `mlyacc` combines handling of side effects with its error correction. Normally, one would have some sort of updatable symbol table that the parser would write to when it encountered a `typedef` declaration. The lexer would read from the same table as it encountered identifiers, allowing appropriate categorisation.

The approach taken in the `StrictC` translator is to have the lexer do all of the work, without reference to the parser (see `StrictC.lex`). This *is* possible, but is also convoluted, and involves many updatable variables that are internal to the lexer. The basic idea is that when the lexer sees a `typedef` token, it switches to the TDEF state. When an identifier is seen in this state, the identifier is added to the list of *typedef-names*, and lexing can continue. The complications arrive in declarations like

```
typedef struct s { int fld1; char fld2; } s_t;
```

where the identifiers `s`, `fld1` and `fld2` have to be ignored, and `s_t` taken as the new *typedef-name*. This requires the lexer to handle the matching brace characters, and partly motivates the requirement that `typedef` declarations all occur at the top-level (and not be nested).

28.6.2 GCC `__attribute__` Declarations

The parser handles, but mostly ignores, various gcc-specific extensions, such as `__attribute__`. These are tricky to parse (something admitted by the relevant gcc documentation): users are given almost unlimited liberty to put their `__attribute__` strings anywhere within a declaration.

For example, these three

```
int f(int) __attribute__((__const__));
__attribute__((__const__)) int f(int);
int __attribute__((__const__)) f(int);
```

are all supposed to parse successfully (and have the same meaning). Making this work is rather involved. Most attributes are ignored, but the standalone analysis tool does check that `const` and `pure` attributes are reasonable, given what it knows of how functions may modify and read the global state.
